Children's language development is very rapid during 2–5 years. At 2 years, they can make short, multiword sentences that have a subject and predicate in a more mature manner. For example, a child might say *ice cream is nice* or *want more candy*. 3-year-olds have sufficient vocabulary to meet immediate needs of life. At 5 years of age, a child can communicate complex thoughts with appropriate descriptions. At four, they can use past tense and at five, they can also use future tense. As they grow, they continue to learn new words every day. By the time they enter the school at the age of five, children typically have a vocabulary of 10,000 words or more.

Acquisition of language is significantly dependent on environmental factors such socioeconomic background.

The amount and quality of interactions and communication with children directly influence their language development. Language development is also closely associated with cognitive and emotional development. Children with delayed speech tend to throw tantrums as they are unable to articulate their feelings using expressive language. Delay in language acquisition may also be a sign of mental subnormality. In school, language plays a crucial role in learning. First the child understands language only after which he starts using it for self-expression. This is followed by recognition and reading of letters and words and finally the acquisition of writing skills. The foundation for reading and writing is laid in the preschool stage which is a prerequisite for future academic progress.

### Emotional Development

Emotional experiences are strongly linked to learning. Different children express different emotions in different manners, intensities and frequencies. For example, the frequency with which children smile and laugh seems to vary with the nature of the environment in which they are raised. Appreciation or a positive response to a baby's smile from parents will increase the frequency of the smile. Learning experiences can also elicit and reinforce other emotions like fear, anxiety, etc.

Typically, at the end of 30 months, children start showing shame and embarrassment and at around 3 years, they show guilt and pride too. From age 4 years to 6 years, they are able to conjure only one emotion at a time. They start controlling unapproved emotional expressions and adhere to the socially acceptable ones.

Children in the preschool stage normally experience attraction, passiveness, attachment and affection toward the parent of the opposite sex and jealousy and resentment for the other. Normally, curiosity about genitals and adult sexual organs is demonstrated. At times, masturbation is also seen in young children.

### Social Development

Children begin to adopt behaviors that are approved by their parents in social surroundings. Their imaginative and social play increases throughout this period. In the due course of socialization, the child starts learning the expected standards of behavior, attitudes and skills that are considered appropriate in society. *Play* is instrumental in the child's social, moral and emotional development since it involves physical activity, learning and interacting with peers, understanding and practicing adult roles. Social and moral developmental achievements can be seen in **Table 5**.

### Moral Development

Parental values, surrounding culture and environment influence the child's moral development immensely. Adults expect children to learn these rules and experience satisfaction when conforming to them and emotional discomfort or guilt when violating them. A

child begins learning *wrong* and *right* from the age of two and his learning is reinforced by parental approval. Internalized standards, the *voice of conscience* or the super-ego, restrain the child from doing wrong even when he is alone. The rules are internalized to avoid punishment (physical consequences) and to attain parental love, approval and security.

### Concerns in Preschoolers

Decrease in food intake during this period can cause parental anxiety. The pediatrician can deal with it by providing charts and proper counseling about adequate nutrition for the child. Very active children or slightly hyperactive children are more prone to physical hurt and accidents; hence, parents should be counseled regarding safety precautions. Impulsive children, who are at a higher risk, should be evaluated in detail.

Working parents should be counseled regarding spending quality time with their children. Parents should interact with them using different skills and types of play activities. Telling stories, reading out books, looking at pictures in books, and ample opportunities for the child to express and observing verbal and nonverbal behaviors of parents facilitate language development. Regular communication also helps them gain emotional control and understand social and moral expectations.

Children need guidance to understand what is expected from them. Excessive control can lead to low initiative and lack of confidence, whereas too much flexibility may create anxiety and insecurity due to confusion and lack of control. Corporal punishment and harsh handling that lead to insecurity and anxiety should strictly be avoided. Parental interference in the development of the child's *handedness* should be prevented by counseling. Some toys and books kept before the child can reduce its anxiety during clinical examinations.

Children differ in temperaments, emotional characteristics and the types of responses they give to various stimuli. These inborn temperaments have a great impact on the pattern and quality of the parent-child relationship. Parents may need guidance to understand their child's temperament and best suitable handling. A child with delayed speech who does not like to play with peers, gives poor eye contact and is more engrossed in solo play, must be evaluated in detail to rule out features of autism.

## MID AND LATE CHILDHOOD

### Physical Development

This stage is characterized by major increases in height, weight and build. Genetic makeup, as well as nutrition and exercise, may affect a child's growth. At this age, children usually have steady and strong motor skills. In this age group, i.e., 6–11 years, a steady increase in muscle strength, stamina, body coordination and eye-hand coordination is seen. They can perform many complex activities involving different motor skills, such as playing musical instruments, playing skillful games, like badminton, dancing, bicycling, shooting, etc. Usually they have high endurance and satisfactory balance which can be seen in their sport activities. Good fine motor control is reflected in activities, such as writing neatly, drawing and dressing up appropriately. Body image begins to develop at around 6 years of age and continues in later stages too. Towards the end of this phase, they begin to develop secondary sexual characteristics.

### Cognitive Development

Late childhood is distinctly different in cognitive functions from the preschool age. This period is considered a concrete operational stage by Piaget. Children start operating logically in which they combine different mental functions in a flexible manner to solve

**Table 5** Social and moral development in 3rd, 4th and 5th years

Age	Social development	Moral development
3 years	Begins to engage in complex and dramatic play	Has little concern for and awareness of rules
4 years	Engages in fantasy play to overcome specific fears	Starts learning about rules, starts controlling undesired behavior
5 years	More open and willing for coordinated friendship to achieve successful play Can dress and undress oneself Engages in role plays	Develops great respect for rules set by significant adults for gaining their approval

problems. Logical thinking enables the child to organize objects into hierarchies and categories. They acquire different fundamental skills such as reading, writing, rules of language and basic arithmetic to achieve academic goals. They start understanding the meaning of abstract words like sympathy, surprise, etc. They prepare themselves for more difficult and complex mental functions. The interplay of their emotional worlds and cognitive functions has a great impact on their school performance. A child's cognitive performance can be assessed using standardized assessment tools and by deriving an intelligence quotient (IQ).

### Social Development

In this phase of development, the child enters a formal school set up and faces many challenges. Stable parent-child relationship is the basis of healthy social relationships in later life. The school allows the child to move away from parents successfully and takes the child toward self-reliance and independence. In families, the siblings play the roles of competitors, role models and supporters, whereas in schools, these roles are played by peers. The child also develops social relationships outside of school, which exposes him to different facets of sociocultural life. Internalization of gender-specific roles and an understanding of gender-appropriate behavior take place in this stage. Their understanding of social roles and acceptable and desired behavior develops. Along with outdoor, strategy and word games, they show a preference for same sex playmates. The family environment and quality of relationships with close family members, especially parents, play an important role in social and emotional adjustment.

### Emotional Development

Acceptance by parents, peers and authority figures like teachers help in laying the foundation for the child's emotional well-being. Positive experiences in their world can help them build positive self-concepts, sense of security and feelings of adequacy. Social skills, such as appreciating others, being able to initiate interactions effectively and being able to communicate well play a vital role in social acceptance. Fear of death, ghosts and inanimate objects are commonly experienced in this stage. Curiosity about birth, death and sexual matters are common topics of conversations among peers. Masturbation, exploring their own sexual organs as well as of others is common. Unconditional affection from parents helps them feel secure about their own importance in their parents' lives. Tender emotions such as sympathy, compassion, humor are experienced by them. They start gaining control over the display of emotions, such as jealousy, anger, fear and disgust.

### Moral Development

Approval and disapproval of parents and other authority figures become vital at this stage. Internalization of set cultural and familial rules, approved standards in the given cultural setup and the emergence of a belief system occurs in these years. According to Piaget, children in elementary school begin to develop moral concepts, such as justice, fairness and reciprocity in interpersonal relationships.

### Concern

Children in this age group are highly aware of and sensitive about their physical attributes. Hence, regular physical activity should be recommended. Any disability, deformity or handicap can make significant impression on their self-concept and cause emotional disturbance. This needs to be addressed carefully through professional intervention.

Parents should be made aware that children of this age are vulnerable to sexual abuse. The pediatrician must talk to the parents regarding this so that necessary precautions can be taken. If a child is excessively anxious regarding being separated from his parents, does not mix with his peers and is poor in scholastic progress, he must be evaluated in detail to rule out emotional and cognitive difficulties. Parents may have concerns regarding their child's school-related problems, such as poor academic performance, difficulty in reading, writing, mathematics, behavioral issues, such as lying, aggressiveness, etc. which they may share with the pediatrician. In such cases, further evaluation must be recommended. Gifted children may also need help and guidance in order to keep them challenged adequately.

Parental support, affection, acceptance and guidance are strongly needed for normal emotional, social and moral development. Children of single or separated parents may face emotional and social issues. The pediatrician must assess all areas of the child's functioning and take the required steps to improve the quality of the child's life.

### IN A NUTSHELL

1. Child development refers to the biological, psychological and emotional changes that occur in humans in the period between birth and end of adolescence, as the individual progresses from dependency to increasing autonomy.
2. Development is described in terms of motor, cognitive, language, emotional and social domains in infancy, toddlers, preschool children and school age children.
3. The chapter provides the normal age of attaining various developmental milestones and their upper limits.

## Chapter 20.3

# Approach to Diagnosis of Developmental Delay: Developmental Screening and Surveillance

Sudha Chaudhari

Developmental delay is a term used for a condition in which the child is not developing and/or achieving age-appropriate skills. It refers to a childhood physical or mental impairment or a combination of both, that results in substantial functional limitations in major life activities.

Early identification of developmental disorders is critical to the well-being of children and their families. It is an integral responsibility of the pediatrician who is following up that child. Delayed or disordered development can be caused by specific medical conditions and may indicate an increased risk of other medical complications; it may also lead to further behavior disorders or associated developmental disorders.

Child development is a dynamic process and is often hard to measure. The various streams of development, including gross motor, fine motor, language cognitive and adaptive behavior are interrelated and complex within themselves. Children develop skills variably and show a new skill inconsistently when mastering it. A single test at one point in time only gives a snapshot of the dynamic process, making periodic screening necessary to detect emerging disabilities as a child grows.

A survey by the American Academy of Pediatrics showed that few pediatricians use effective means to screen their patients. It is absolutely mandatory that every *high-risk* infant be screened for developmental delay. In fact, the American Academy of Pediatric recommends that a development screening should be done for every well child at 9, 18 and 30 months visit.

Early identification is important because of the potential for improvement of outcome through educational and rehabilitative services for children with or at risk for developmental delay. In the first months of life, abnormal development is indicated by a poor suck, floppy or spastic tone and a lack of visual or auditory response to environmental stimuli. Later, in the first year, motor delay in sitting or crawling and in the second and third years, language and behavioral abnormalities point out to a problem in development.

## DEVELOPMENTAL ASSESSMENT

Early identification has a three-pronged approach—a birth and developmental history, a physical and neurologic examination and developmental screening. Birth history and other adverse prenatal and perinatal events, maternal illness, substance abuse, consanguinity and sociocultural background are important. The presence of multiple risk factors increases the chance of developmental disability.

**Developmental history** A history of delayed or uneven acquisition of milestones in any sphere of development including cognition, fine or gross motor skills, speech and language, adaptive skills and psychosocial skills should alert the pediatrician to the need for further evaluation.

**Physical examination** The general physical and neurologic examination is an integral part of the evaluation of the child.

Dysmorphism, growth abnormalities, major and minor congenital anomalies, skin or eye findings and organomegaly may give a clue. Neuromotor delays may be the presenting feature of several genetic disorders.

**Neurologic examination** A classical neurologic examination may not be enough in children with developmental delay. Some special examination methods like the one described by Amiel-Tison will yield information that is more useful for rehabilitation.

## Hearing and Vision Screening

Hearing and vision screenings should be a routine in the examination of a child. Visual tracking can be checked with a red ball and hearing can be assessed by using a bell. The cause of hearing loss may be related to the etiology of developmental disability (congenital cytomegalovirus infection, microcephaly). Children at high risk for hearing impairment include premature infants, children with cerebral palsy and children with some genetic syndromes.

## Developmental Screening

Studies have demonstrated that pediatricians are unreliable in determining the presence of developmental delay from clinical judgment alone. Hence a standardized screening test must be used. The most effective method for development screening by a busy pediatrician is a combination of a historical review of milestones (in comparison with established norms), observation of development skills using a standardized screening tool and the neurologic examination.

## ALGORITHM FOR DETECTING DEVELOPMENTAL DELAY

(Based on the Recommendations of American Academy of Pediatrics)

### Pediatric Patient at Well-Baby Clinic Visit

Every child attending the well-baby clinic must have a developmental examination (**Flow chart 1**). Many children may have risk factors at birth which may lead to delayed development. Some children may show delayed development in early childhood. If these are not detected and treated early on, the children may end up with social and emotional problems and school failures. Some specific medical conditions may have delayed development, for which there may be medical treatment. Early intervention may help in a wide range of developmental disorders.

## Surveillance

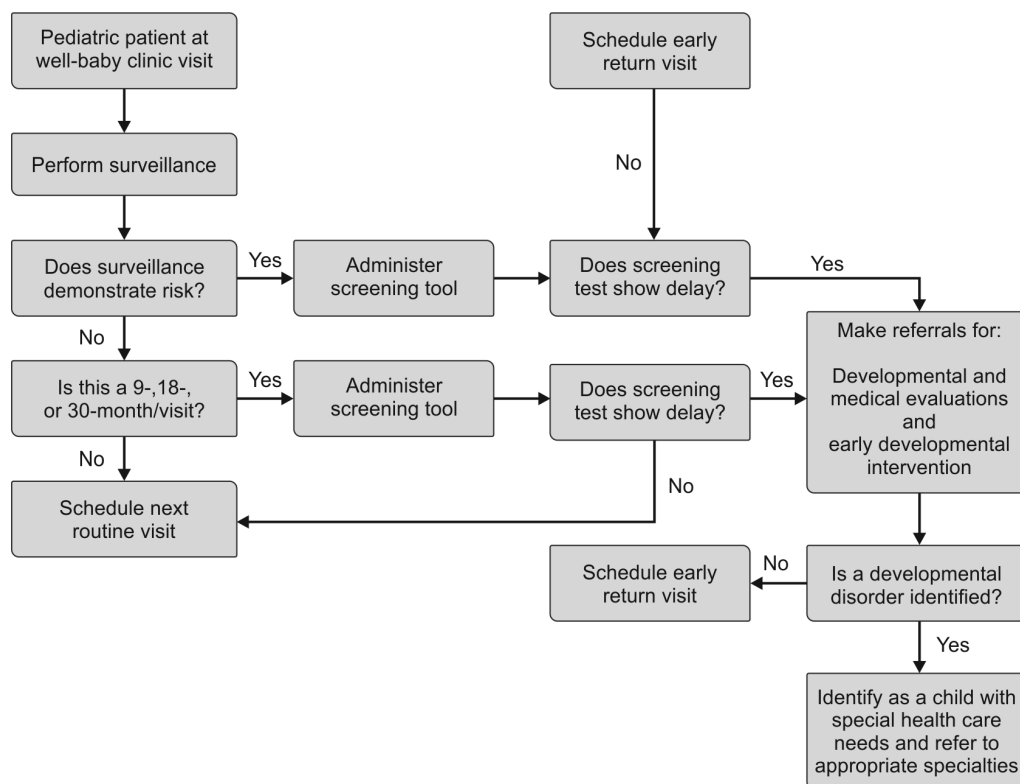

Pediatricians can identify children who may have developmental problems by continuous surveillance and vigilance. Surveillance will result in appropriate referrals, patient education and promotion of healthy development. There are five components of developmental surveillance.

### Parents' Concerns

Educated parents have sharp observational skills. The pediatrician must give serious attention to parental concerns about their child's development. Asking specific questions about the child's behavior may give a clue regarding the child's development because development and developmental delays are often manifested by the child's behavior. Sometimes a child may have a major delay and the parents show no concern, probably because of lack of knowledge about developmental milestones.

### Developmental History

Developmental history taking should be a routine part of the well-baby visit. Age-specific questions such as voluntary reach for a

**Flow chart 1** Developmental surveillance and screening algorithm during a well-baby clinic visit

Adapted from: Council on Children with Disabilities, Section on Developmental Behavioral Pediatrics, Bright Futures Steering Committee, Medical Home Initiatives for Children with Special Needs Project Advisory Committee. Identifying infants and young children with developmental disorders in the medical home: an algorithm for developmental surveillance and screening. *Pediatrics*. 2006;118:405-20.

toy, independent sitting, crawling can be asked to ensure that the child is acquiring skills at the right age. Equal attention should be given to deviations in development, whereby children develop skills out of sequence in conditions, such as cerebral palsy and autism. Normal motor skills and delayed language development may be seen in children with autistic spectrum disorder or mental retardation. Children with spastic diplegia have normal language skills with motor delay. Regression of motor skills suggests some serious neurologic problem.

### Observation of the Child

A careful physical and developmental examination must be done at every well-baby clinic visit.

### Presence of Risk and Protective Factors

Assessment of risk factors is an important aspect of surveillance. The risks may be biological, genetic, social or environmental. The presence of more than one risk factor may increase the chances of developmental delay. Children with known risk factors may require more frequent developmental surveillance or may be directly referred for developmental assessment. A loving, educated, supportive family, where the child grows up in a warm, conductive environment is an important asset in a child's life. Environment plays a major role in a child's development.

### Documentation

Milestones should be documented properly at each visit.

### Demonstration of Risk

If the parents express concern about the child's development, the child should be referred directly for a development test. Similarly, if the pediatrician feels during surveillance that the child is at risk for developmental delay, a screening test may be required. If the screening test is normal, the parents may be reassured, but surveillance should be continued.

### Periodic Development Screening

Development may be proceeding normally and there may be no known risk factors, but it is worthwhile to do a periodic developmental screening test. The American Academy of Pediatrics recommends screening at 9, 12 and 18 months.

- *Nine months of age:* Many motor skills are evolving at this age. Hearing and vision can be reliably tested at 9 months. Important aspects of communication and language skills such as vocalization, gestures are obvious at this age. Since language, motor and cognitive skills develop rapidly at this age, parents should be asked if they have concerns in these areas of development.
- *Eighteen months of age:* Language and communication delays are very obvious at this age. Hence early intervention and speech therapy may be started. Mild motor delays which were not picked up at 9 months, may become apparent at 18 months and intervention can be started.
- *Thirty months of age:* Motor, language and cognitive delays are easily identified at this age using screening tests and intervention can be started immediately.

When pediatricians use only their clinical impression to diagnose developmental delay instead of using a screening test, their impressions are not accurate many a times. Hence, screening tests must be used to improve the precision in diagnosis of developmental delay.

### Screening Test

It is a brief standardized test which helps in identifying children at risk of a developmental disorder. Screening tools like ages and stages questionnaire can be completed by moderately educated parents and the answers can be scored even by a non-physician. However, the final interpretation must be done by the pediatrician. The screening test does not give a diagnosis but merely identifies areas in which the child is lagging behind. Screening tests should be given periodically. If we wait for the child to miss a major milestone like walking or talking, it may be too late and we will be depriving the child of the benefits of early intervention.

### Screening Test Results

If the screening test results are normal, this can be told to the parents and relieve them of their anxiety. If the results are not normal, the child should be referred immediately for more elaborate developmental tests and medical evaluation.

### Developmental Evaluation

Diagnostic developmental evaluation should be done when the screening test is not normal. This evaluation aims at making a specific diagnosis of the development disorder, for counseling the parents regarding prognosis and referring the child immediately for proper therapeutic intervention. These children may have other associated developmental and behavioral problems and these will also have to be treated. An interdisciplinary team consisting of a psychologist, occupational therapist and audiologist will be needed.

### Medical Evaluation

A medical evaluation consisting of biological, environmental and other risk factors for delayed development must be done in an attempt to establish an etiology. Screening of vision and hearing, review of neonatal metabolic screen, growth, family and social history may give a clue to the etiology.

A detailed medical evaluation and additional tests like brain imaging, electroencephalogram, metabolic screen and genetic screen may be required. The parents find it easier to accept the child's disability once the etiology is explained to them. This also helps in treatment, planning, genetic counseling for recurrence and prognosis. It is reported that an underlying etiology will be identified in approximately one quarter of cases of delayed development, with higher rates (> 50%) in children with global delays and motor delays, and lower rates (< 5%) in children with isolated language disorder.

This evaluation can be done by a trained and skilled pediatrician, a developmental pediatrician, pediatric neurologist and, if required, a pediatric geneticist. When a child is identified as having developmental delay, early intervention is mandatory.

### Developmental Disorder

The child can be referred for appropriate therapy if a developmental disorder is identified.

### Referral to Rehabilitation Services

When a child is identified to have developmental delay, the child should be referred to a center which has specialized services. The pediatrician should be aware of the centers in the local area where

psychologists, occupational therapists, audiologists and other such facilities are available for testing and therapy. Unfortunately, there are very few such centers in India.

### THE HIGH-RISK INFANT

The *high-risk* infant is one who is at risk for having a developmental disability. The number of high-risk infants is increasing day by day since we are saving many extremely low birthweight babies, with all the new technological advances. The risk factors may be biological or environmental, or there may be an overlap of both. Some risk factors carry a much higher risk of developmental delay than others. The biologic risk factors are: (i) prematurity; (ii) low birthweight; (iii) intrauterine growth retardation; (iv) hypoxic ischemic encephalopathy; (v) congenital brain abnormalities on imaging; (vi) biochemical abnormalities (hypoglycemia, hyperbilirubinemia; (vii) sepsis/meningitis; (viii) congenital infections; (ix) respiratory distress needing ventilation; (x) seizures; (xi) intracranial hemorrhage; and (xii) maternal substance abuse.

It is absolutely mandatory that a *high-risk* infant be followed up very closely. Besides monitoring the growth and nutrition, a developmental examination at least in every 3 month this is recommended. It is important to use the corrected age while assessing preterm infants. Parents of *high-risk* infants sometimes tend to overrate skills of their children. Hence, the pediatrician should do a good developmental examination, especially of the motor skills.

Pediatricians can elicit key clinical information about a child's motor development from the parents by asking them broad open-ended questions (**Table 1**).

Children with increased tone may attain motor milestones early, asymmetrically or *out of order* like standing before sitting or development of handedness before 18 months. Children born with developmental defects present with developmental delay. Children who show regression of milestones should be investigated for neurodegenerative disorders.

The environmental risk factors are low socioeconomic status, poor maternal education and a single parent. In the *Pune low birthweight study—Birth to Adulthood*, babies who were preterm and small-for-gestational-age (SGA) with double biologic risk factors of prematurity and intrauterine growth restriction, had the lowest intelligence quotient (IQ). But preterm SGA children in the higher socioeconomic group and with college educated mothers had higher IQs at 18 years compared to those from the lower socioeconomic group and mothers with only primary school education (**Fig. 1**).

**Table 1** Key elements of the motor history

Key elements of motor history	Example
Delayed acquisition of skill	Is there anything your child is <i>not</i> doing that you think he or she should be able to do?
Involuntary movements or coordination impairments	Is there anything your child is doing that you are concerned about?
Regression of skill	Is there anything your child used to be able to do that he or she can no longer do?
Strength, coordination and endurance issues	Is there anything other children of your child's age can do that is difficult for your child?

Source: Adapted from Noritz GH, Murphy NA and Neuromotor Screening Panel. Pediatrics. 2013;131:e2016.

**Figure 1** Maternal education and IQ (Standard Progressive Matrices) at 18 years  
 Abbreviations: IQ, intelligence quotient; SGA, small-for-gestational-age; LBW, low birthweight; PT, preterm.

## EARLY INTERVENTION

It implies a system of programs that work with an infant and his or her family to prevent or minimize adverse outcomes in the child. Although a number of studies have demonstrated beneficial effects of early intervention programs, there is no convincing data to suggest that it prevents disability. Nevertheless, many feel that early intervention strategies do help in minimizing secondary complications and generally support the parents through a difficult time of uncertainty and coming to terms with their child's disability. Intervention is most important when it occurs at the time that a developmental skill should be emerging.

We recommend that a neurodevelopmental examination be done at corrected age (chronologic age + weeks of prematurity) of 3, 6, 9, 12 and 18 months and a development quotient (DQ) be done at 18 months to see the motor and especially the mental development.

The development of preterm infants is quite different and has more variability compared to full term infants. It is important to understand the deviations in the development of preterm infant lest you make a rash diagnosis of cerebral palsy. It is reported that 60% of preterm babies have tone abnormalities. However, the brain has tremendous plasticity, and by 9 months, many of these tone abnormalities disappear and tone normalizes by 1 year. These are termed as *transient tone abnormalities*. Chaudhari et al. have reported that 41% very low birthweight infants had transient tone abnormalities, but their cognitive outcome at 5 years was normal. This is why one should never make a diagnosis of cerebral palsy at the first examination, but several sequential examinations should be done over a period time.

One of the best tests for diagnosis of tone abnormalities is the neurological assessment described by Amiel-Tison. Evaluation of tone is the fundamental part of this assessment. The waxing and waning pattern of neuromotor development from 28 weeks to the end of first year should be clearly understood. For example, from 28 weeks to 40 weeks of gestation, the acquisition of muscle tone and motor function spreads from the lower extremities to the head (caudocephalic). After full term, the process is reversed, so that relaxation and motor control proceed downward for the next 12–18 months (cephalocaudal; **Fig. 2**).

Examination of skull and ocular signs must be looked for. Neurosensory development is assessed by noting visual pursuit with a red ball and hearing with a bell. History of convulsions,

sleeping pattern, quality of cry and sucking and swallowing behavior should be noted.

The evaluation of tone is based on the study of (1) spontaneous posture; (2) passive tone; and (3) active tone. Spontaneous posture is studied by inspecting the child while he or she lies undisturbed (**Fig. 3**). Axillary suspension of the child should be done before assessing the tone. A hypotonic infant will slip through the hands, a spastic infant may spontaneously scissor (**Fig. 4**).

Passive tone is evaluated by applying certain maneuvers to an extremity. The resistance of the extremity to these maneuvers is measured as an angle. The angles are the same as those used in the Dubowitz gestational age score, like the adductor angle, popliteal angle, scarf sign, square window, etc. These angles have been standardized by us on normal Maharashtrian infants and are quite similar to those described for Caucasian French infants.

Active tone is studied with the infant moving spontaneously in response to a given stimulus like pull to sit or pull to stand.

Brisk tendon reflexes and clonus are noted. While eliciting ankle clonus, one must look for Achilles tendon tightness because this will make the child do *toe-walking*. (**Fig. 5**)

The persistence of primitive reflexes like asymmetrical tonic neck reflex (**Fig. 3**) is especially looked for. Fisting and cortical thumb are also noted. The appearance of postural reactions like lateral propping and parachute at the right age is also noted. All this information put together makes it a complete neurological examination.

The main drawback of this method is that it does not take mental development into consideration and hence does not replace developmental tests. It is a good screening test to identify infants who need occupational therapy and to decide which infants need to be referred for the more elaborate developmental tests. Chaudhari et al. reported that if the 3 months assessment by Amiel-Tison was normal, the predictive value for a normal 12 months motor development was 93.6%.

## INVESTIGATIONS

Investigations aim at establishing a possible etiology underlying the child's specific developmental delay. The etiology may or may not be apparent at the end of the clinical examination. Determining the underlying etiology is important for many reasons. It imparts an understanding of the pathogenesis to the family, answering their *need to know why*. In genetic conditions, it has implications regarding recurrence risk. It also allows for

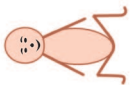

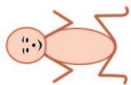

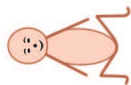

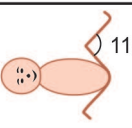

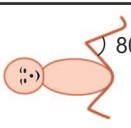

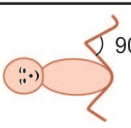

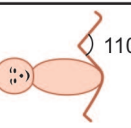

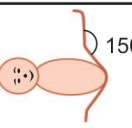

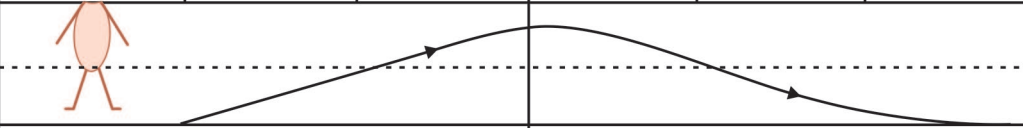

Posture					
Scarf sign					
Popliteal angle					
					
Increasing muscle tone in a caudocaudocephalic wave			Decreasing muscle tone in a cephalocaudal wave		

Figure 2 Evolution of passive tone

Figure 3 Spontaneous posture—persistence of asymmetric tonic neck reflex and scissoring

Figure 4 Scissoring on axillary suspension

more accurate prognostication. Karyotyping may be ordered when there are dysmorphic features. Neuroimaging (Figs 6 and 7) is likely to identify an etiology when it is suspected clinically—microcephaly, tone abnormalities, history of birth asphyxia. Electroencephalography may be done when the child has seizures. Investigations for inborn errors of metabolism should be ordered judiciously. Every child need not have an array of expensive tests and investigations.

## DEVELOPMENTAL TESTS

A summary is provided in Table 2. Individual tests are discussed below in brief.

### Ages and Stages Screening Questionnaire

The ages and stages screening questionnaire (ASQ) is a parent-completed child development screening test with 19 questionnaires

ranging from 4 months to 60 months that are identical in format and organized into five-item domains (communication, gross motor, fine motor, problem-solving and personal-social). Questions can be answered by parents with 7th grade education. For those with low literacy level, it can be administered as an interview. Parents indicate *yes*, *sometimes* or *not yet*. The ASQ needs 15 minutes to complete and 2–3 minutes to score. It has moderate to high sensitivity and specificity. Juneja et al. have used a Hindi translation of the test with good results.

### Trivandrum Development Screening Test

This test can be used in the first 2 years of life. Seventeen test items including motor and mental items were chosen. The range for each test item was taken from the Indian adaptation of Bayley Scales of Infant Development (Baroda Norms) Test. The main shortcoming of this test is that the Denver Developmental Screening Test (DDST) was used as the gold standard, which in itself is a screening test.

**Figure 5** Spastic infant *toe-walking*

### Denver Developmental Screening Test

This test is a screening test of cognitive and behavioral problems in the age group of 0–6 years. Tasks are grouped into four categories (fine motor skills, gross motor skills, social contact and language). In this test, a subject's performance against the regular age distribution is noted. This test is widely used all over the world. But it has been criticized for being unreliable in predicting less severe or specific problems in children, resulting in underreferrals. The test depicts in graphic form the ages at which 25%, 50%, 75% and 90% of children performed from birth to 6 years. It enables the examiner to visualize at any age how a child's development compares with that of other children.

### Developmental Assessment Scale for Indian Infants

The Bayley scale was standardized by Phatak for Indian infants. This test consists of 163 mental items and 67 motor items. Both the scales express the child's performance by the number of items passed by the child. A DQ more than and equal to 85 is considered as normal. The test must be administered by a trained psychologist, it needs a special kit and must be ideally performed in a soundproof room. This test is considered as the gold standard for assessing development.

### Bayley III

A new and much longer version of the Bayley scales, it covers the age group of 16 days to 42 months. It covers 5 domains—language, cognitive, fine and gross motor and socioemotional. It takes 30 minutes administration time for children below 13 months and 50 minutes for children 13 months and above. This test has been criticized because it yields higher than expected scores which may lead to underreferrals.

Early identification of children with developmental delays or disabilities can lead to early intervention and treatment and lessen its impact on the child. Developmental surveillance is an important way of detecting developmental delays. The pediatrician should be skilled in the use of screening techniques, carefully listen to parental concerns, and create links with available resources in the community.

**Figure 6** Migrational defect—Polymicrogyria in a term neonate. Thick gyri in bilateral frontal regions with paucity of sulcal spaces

**Figure 7** Corpus callosal agenesis

### IN A NUTSHELL

1. Early identification of developmental delay has a three-pronged approach: a birth and developmental history; physical and neurologic examination; developmental screening.
2. According to the American Academy of Pediatrics, every child attending the well-baby clinic should have a developmental examination at 9, 18 and 30 months.
3. The pediatrician should give serious attention to parental concerns about their child's development.
4. The pediatrician should familiarize himself with a simple screening test.
5. When a child is identified to have developmental delay, early intervention is mandatory.
6. The child with developmental delay must be referred to a center which has specialized services with multidisciplinary team.
7. The *high-risk* infant should be monitored very closely for developmental delay.

**Table 2** Summary of developmental tests

Test	Age	Assessment	Development index	Usefulness	Limitation
1. Ages and Stages Questionnaire Screening Test (ASQ)	4–60 months	Parent completed questionnaire. 19 age-specific questions. Gross motor, fine motor communication, problem-solving, personal, social (pass, fail)	Quantitative sensitivity, specificity moderate to high	Can be used as a screening test in a well-baby clinic	Depends on intelligence and observations of the parents
2. Trivandrum Development Screening Chart (TDSC)	0–2 years	17 items from the Bayley scales are used, motor and mental items	Sensitivity, specificity moderate	Can be used as a screening test in a well-baby clinic	DDST used as a gold standard, which in itself is a screening test
3. Denver Development Screening Test (DDST)	0–6 years	Motor behavior. Adaptive behavior, personal and social behavior, language development, risk category (normal, questionable, abnormal)	Quantitative, low to moderate sensitivity, specificity	For use in a busy clinic	Misses mild delay, resulting in underreferrals
4. Developmental Assessment Scale for Indian Infants (DASII), Adaptation of Bayley II Scales of Infant Development	0–30 months	Mental (163 items) Motor (67 items) Considered to be gold standard	MeQ $\geq$ 85 normal MoQ $\geq$ 85 normal 70–84 delayed development < 70 retardation	Confirmatory test after screening tests have identified delay	Needs a trained psychologist and a soundproof room and a special kit
5. Bayley III Much longer test Takes 30 minutes for children < 13 months and 50 minutes $\geq$ 13 months	16 days to 42 months	Covers cognitive, language, fine and gross motor and socioemotional development	Higher scores compared to Bayley II	Needs further validation before use in Indian children	Gives much higher scores hence may lead to under referral

Abbreviations: MeQ, mental quotient; MoQ, motor quotient.

## Chapter 20.4

# Global Developmental Delay

Madhuri Kulkarni, Mona P Gajre

Neurodevelopmental disabilities are chronic clinically distinct disorders that share disturbances in developmental process in different developmental domains compared with established norms. The various developmental domains are motor (gross, fine), speech and language, cognition, personal-social and activities of daily living. These domains are not mutually independent and often development in one domain is a prerequisite for the development in other domains. The developmental disabilities are diagnosed over time rather than at a single point of clinical interview.

### DEFINITION

Global Developmental Delay (GDD) is a symptom complex with heterogeneous etiology. It is a developmental disability having essential feature of predominant disturbance in acquisition of skills in two or more domains of cognitive, motor, language or social development. These disturbances significantly impact on developmental progress of an individual.

The terms GDD and intellectual disability are part of the same spectrum. These are now preferred over the previously used *mental retardation*. American Association of Mental Retardation in 2000 defined mental retardation as *a disability characterized by significant limitation both in intellectual functioning and in adaptive behavior as expressed in conceptual, social, practical and adaptive skills*. Assessment of level of intellectual functioning needs measuring intelligence which is problematic in a child younger than 5 years. In older children, intelligence quotient (IQ) testing is more reliable and valid. The infants and young children are rapidly progressing concurrently through various developmental domains. Therefore, for the young child, the term *global developmental delay* is used to describe a disturbance across variety of developmental domains.

The American Academy of Neurology defines GDD as a significant delay in two or more of the following developmental domains, e.g., gross/fine motor, cognitive, speech/language, personal/social and activities of daily living.

According to Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), the diagnosis of GDD is reserved for individuals under 5 years of age when the child fails to meet expected developmental milestones in several areas of intellectual functioning. It applies to children who are unable to undergo systematic assessment of intellectual functioning, or are too young to participate in standardized testing.

Many children meriting the diagnosis of GDD in the preschool years, when assessed later at school age, continue to meet diagnostic criteria for GDD. Many older children diagnosed with intellectual disability were initially diagnosed on retrospective review with GDD. Thus, these entities share common features and both represent learning continuum. However, a diagnosis of GDD does not necessarily imply intellectual disability in future. A variety of disorders, such as cerebral palsy, congenital muscle disorders, autism spectrum disorder and environmental deprivation might, in fact, be associated with normal cognitive potentials.

### PREVALENCE

Developmental disabilities are reported to be a common problem in child health clinics affecting 5–10% of preschool age children in

North America. A national sample of 9,854 children of 2–3 years age studied in Israel showed a disability rate of 8.9%. In a house to house survey of 3,560 children, 0–6 years of age at Delhi, disability rate was 6.8%. Prevalence of developmental delay, deformity or disability was found to be 2.5% in children below 5 years of age in a rural Kerala study. The common disabilities observed in the same study were speech and language problems 29.8%, vision and hearing problems 22.2%, cerebral palsy 12.2% and mental retardation and related disorders 8%.

### ETIOLOGY

The etiological factors causing GDD are classified as prenatal, perinatal, postnatal and undetermined causes (**Table 1**). The largest category in most studies is prenatal including genetic and acquired. Causes such as low birthweight and prematurity are considered to be risk factors for GDD. In India, birth asphyxia leading to hypoxic-ischemic encephalopathy, and perinatal infections are commonly observed causes. The postnatal causes include infections, trauma, stroke and exposure to toxins.

Several studies have reported wide variation in the etiologic yield for children who have GDD. These variations reflect differences in sample population characteristics, the method of classification, and diagnosis of neurodevelopmental disability in addition to availability of genetic and imaging technology. The Finnish classification of etiology is based on the timing and type of injury to the central nervous system (CNS). Six broad groups described in this classification are (i) genetic causes (e.g., single gene defect, chromosomal abnormalities, and recognizable syndromes); (ii) CNS malformation; (iii) external prenatal factors; (iv) perinatally acquired disorders; (v) postnatally acquired disorders; and (vi) unclassified causes.

Approximately, one-third of etiological diagnoses can be made by history and examination alone. Laboratory testing is used to confirm a diagnosis suspected on the basis of history and examination in another one-third. In the remaining third, etiologic diagnosis is made on the basis of laboratory testing alone. Significant progress has been recently achieved in identifying underlying etiology, using a variety of laboratory tests including neuroimaging and genetic and metabolic investigations. Searching for and determining a specific underlying etiology has important implications with reference to ongoing management-related issues like recurrence risk, accurate prognostication, mechanism of medical follow-up and specific therapeutic interventions. GDD was observed in 44 of 80 (55%) children under 5 years of age referred to ambulatory pediatric neurology

**Table 1** Causes of global developmental delay

Period	Causes
Prenatal	Genetic—chromosomal defects, single gene defect, nonsyndromic gene defect, metabolic disorder Acquired—maternal infections, nutritional deficiencies, fetal alcohol syndrome, maternal substance abuse
Perinatal	Birth asphyxia leading to hypoxic-ischemic encephalopathy Infections Stroke Metabolic disturbances
Postnatal	Infections leading to meningoenitis Trauma Stroke Severe malnutrition Psychosocial deprivation

and developmental pediatric clinics. Etiologies determined in these children included cerebral dysgenesis, *hypoxic ischemic encephalopathy*, toxin exposure, chromosomal abnormalities, psychosocial neglect, neuromuscular disorder, genetic syndromes and other causes.

In a study carried out in Northern India, 66 (54.1%) out of 122 children with developmental disabilities could be assigned a definite etiology and 38 (31.1%) a probable etiology. Amongst 66 children with definite etiology, 17 were prenatal, 38 perinatal/neonatal, and 11 postnatal in origin.

## EVALUATION

The main objective of evaluation of a child with GDD is to confirm the delay and plan the intervention. More than one visit may be required for complete evaluation. The principle elements include:

- Confirming and classifying the neurodevelopmental delay
- Establishing possible etiology through interview, observation, examination and selective laboratory testing
- Identifying the needed rehabilitation and intervention programs
- Counseling of family regarding implications of the disorder and the possible outcomes
- Exploring role of pharmacotherapy for comorbidities (seizure disorders, attention deficit, sleep disturbances, spasticity and behavioral concerns).

## Interview

Assessment of a child with interview of the parents involves recording the history, observing the child and performing detailed physical and developmental examination. The verbal children should also be included in the interview process.

A three-generational comprehensive family history, with possible consanguinity, previous fetal, neonatal deaths, maternal pregnancy details are to be inquired as they may provide invaluable data. A special emphasis on maternal age, adverse antenatal events such as per vaginal bleeding, gestational diabetes, number of antenatal visits, weight gain, medication history, use of tobacco, alcohol should be inquired. The intrapartum history of duration of labor, mode of presentation and resuscitative measures requirements should be noted. History of adverse events during labor or delivery such as meconium staining, premature rupture of membranes, need for cesarean section is also important. Objective measures of neonatal well-being such as birthweight, appearance, pulse, grimace, activity, respiration (APGAR) scores, gestational age, postneonatal stay, feeding pattern, occurrence of neurologic symptoms, abnormal urine order, breathing problems are also noted. These provide important clues to the origin of a child's developmental condition to a prenatal or perinatal event. Subsequently the child's detailed medical history of medical admissions, treatment history, chronic ongoing medical condition needs to be documented. The effect of psychosocial deprivation on the child's development is huge; in this context, parental neglect, abuse, caregiver emotional status have to be determined.

After this important background information, the developmental history can be properly placed into an individual, familial and social context. The precise developmental domain and the age of the child when parental concerns were noted are extremely valuable to proceed further in evaluation. Developmental history with regard to achievement of skills in the motor, language, social/play domains has to be recorded. In this context, pictorial evidence, home videos records are valuable tools. Linking the emergence of a milestone to an important event in the child or parents life (e.g., first birthday party) is often useful. Although not encouraged, sometimes comparing the index child developmental trajectory

with their siblings is often handy especially to know the pace of skill acquisition over time; specifically any loss of developmental skills or functions should be recorded. Current performance in each domain is ascertained in addition to key activities of daily living, such as toileting, dressing, feeding and self-hygiene in the older child.

Possible coexisting conditions, like autistic features, such as poor eye contact, repetitive behaviors, inappropriate social and communication interactions should be asked. Additionally presence of disruptive behaviors, food and sleep hygiene, should be inquired.

The neurodevelopment assessment is to be done by observation of the child and also the family during the interview process. It is facilitated with provision of a child-friendly environment with age appropriate playthings. Observing the child's interaction with them in a nonthreatening manner, with the presence of a caregiver can give invaluable insights into the developmental level of various domains. Additionally, it is of utmost importance to interact with the child to assess his cognitive and language skills, such as identifying pictures, body parts, colors, shapes, story-telling capabilities. Vocabulary can be assessed by child's spontaneous speech, response to direct questions can also provide a clue to semantic and syntactical capabilities. Comprehension is assessed by understanding of multistep complex commands. Cognitive skills can be assessed by the child's grasp of specific concepts, use of objects. Gross motor skills are assessed by direct observation, gait analysis, ball playing activities, whereas fine motor skills are tapped into through the use of blocks, by specific pen and paper tasks such as copying shapes, figure drawing, precision for activities of daily living.

## Physical Examination

It is critical to ascertain the corrected gestational age for preterm babies for appropriate diagnosis of delay till 2 years of age. Physical examination is essential for the diagnostic workup of the child with GDD. Physical development for maturity includes height, weight and head circumference measurements. The height and weight are plotted on the age- and gender-appropriate percentile. Microcephaly suggests poor brain growth, low set ears suggest fetal pattern of posterior ear rotation, a high-arched palate is indicative of oral motor dysfunction. Presence of microcephaly (less than third percentile) mandates obtaining and plotting the parent's head size; checking previous records for the evolution of the head size over time is critical. Dermatologic assessment for *café-au-lait* spots suggestive of various neurocutaneous syndromes is essential. Examination of the spine should be undertaken for any defects or overlying cutaneous abnormalities that suggest a spinal dysraphism.

Neurologic examination is crucial and clues to diagnosis may be provided by abnormalities of tone, power, deep tendon reflexes, cranial nerves examination and coordination. Presence of extrapyramidal movement abnormalities especially dyskinesias such as tremor, dystonia, chorea or athetosis should be documented. The gait of the child is noted in detail, tests of manual dexterity such as grasping objects, throwing and kicking a ball, jumping or hopping on one foot is also noted. Presence of soft neurological signs like dysdiadochinesia, sequential hopping, left and right orientation issues, balance issues suggest neurological immaturity.

## Developmental Assessment

Neurodevelopmental assessment includes the 180 degrees flip test for posture, tone, coordination in different maneuvers such as supine, pull to sit, axillary and ventral suspension and in prone

position. Elicitation of primitive reflexes, such as oral reflexes, Moro reflex, grasp reflex, asymmetric tonic neck reflex, parachute reflex, are useful in assessing the developmental age. Persistence of primitive reflexes is a possible sign of several conditions including cerebral palsy, autism, and speech dysfunction. Importantly, their persistence interferes with development of postural control, mobility and achievement of motor milestones. Role of Amiel-Tison test to assess active, passive muscle tone in various maneuvers is highly informative. It essentially classifies the babies into normal or persistent abnormal tone patterns.

The *red-flag* signs for delays in certain domains are listed in **Table 2**.

A key part in the second follow-up visit of a developmentally delayed child is to exclude the possibility of a progressive encephalopathy or neurodegenerative process. **Table 3** lists the various screening and confirmatory tools available in India which can be easily used for evaluation of children with GDD. The commonly used tools have been already discussed in the previous chapter.

### Laboratory Investigations

The heterogeneity of GDD with a wide-ranging etiology invokes the possibility of extensive laboratory investigations and the choice of tests is often challenging. There is no *one size shoe fits all* algorithms for evaluation of GDD and investigations need to be individualized for a rational approach.

The laboratory investigations should be planned as per the specific clinical diagnosis suspected, based on history and clinical examination. Thus, in children with a history of adverse perinatal events or in those with abnormal neurological findings, seizures or microcephaly, neuroimaging should be undertaken. A high-resolution MRI is preferable to a CT scan. Cytogenetic studies are indicated in children with dysmorphism. If a specific syndrome is suspected, such as Prader Willi or Angelman syndrome, a targeted fluorescent in situ hybridization probe should be done, for a Fragile X syndrome, FMR triplet repeat testing should be done. On suspicion of Rett syndrome, MECP2 gene analysis studies can be done. Additionally, chromosomal microarray may be indicated in some case.

At present, unselected metabolic screening in all cases of GDD is not justified as it has poor yields. In presence of clinical clues such as: (1) a prior family history of an affected child; (2) consanguinity; (3) developmental regression; (4) episodic decompensation; (5) dysmorphism; (6) ophthalmologic or retinal abnormalities; (7) nonscreened newborn; and (8) neuroimaging findings of basal ganglia involvement in the absence of asphyxia or unexplained white matter changes also necessitate a metabolic testing. Metabolic testing involves blood gases, serum lactate, serum ammonia, liver function tests, serum amino acids, urine organic acids, serum carnitine and very long-chain fatty acids levels. The association of multisensory impairments mandates visual and hearing assessments. Hearing screening requires auditory evoked response testing or formal audiometry. A visual evoked potential study can be done in retinal abnormalities. Electromyography or nerve conduction studies are indicated if a possibility of a neuromuscular disorder exists. Electroencephalogram is done in situations of a suspicion of paroxysmal events such as seizures.

*Hypothyroidism* is a common cause of GDD in goiter-endemic areas and early screening with thyroid hormones levels, such as T3, T4, TSH, has been recommended. Serological testing for Toxoplasmosis, Other (syphilis, varicella-zoster, parvovirus B19), Rubella, Cytomegalovirus, Herpes (TORCH) and human immunodeficiency virus infection is essential in infants with maternal history of such infections, in low birthweight infants, and

**Table 2** Red flag signs for developmental delay

Developmental domain	Clinical features
Gross motor delay	<ul style="list-style-type: none"> <li>• Tone abnormalities: Hypotonia, hypertonia, dystonia</li> <li>• Asymmetry/dysmorphology</li> <li>• Persistence of primitive reflexes</li> <li>• Abnormal deep tendon reflexes, clonus</li> <li>• Hand preference in less than 18 months</li> <li>• Abnormal gait</li> </ul>
Fine motor delay	<ul style="list-style-type: none"> <li>• Immature grasp till 1 year</li> <li>• Poor manipulation of objects till 1 year</li> <li>• Eating with excessive spillage after 15–18 months</li> <li>• Excessive clumsiness after 2 years</li> <li>• Assistance in dressing beyond 3 years</li> <li>• Uncontrolled scribbling beyond 3 years</li> <li>• Difficulty buttoning the shirt by 4–5 years</li> </ul>
Speech delay	<ul style="list-style-type: none"> <li>• No babbling: 12 months</li> <li>• No pointing or gesturing: 12 months</li> <li>• No single words: 16 months</li> <li>• No two-word phrases: 24 months</li> <li>• Unintelligible speech: 24 months</li> <li>• Regression of language skills: any age</li> <li>• Loss of language or babbling</li> <li>• Loss of social skills</li> </ul>
Cognitive delay	<ul style="list-style-type: none"> <li>• Difficulty in following simple instructions</li> <li>• Poor comprehension skills</li> <li>• Difficulty in learning new skills</li> <li>• Poor expressive language</li> <li>• Poor memory recall and actual sequence of events</li> <li>• Behavioral problems</li> <li>• Academic lags</li> <li>• Slow in activities of daily living</li> <li>• Poor self-help and increased dependency</li> </ul>

**Table 3** Tools for evaluation of early developmental delay

Domain	Screening tool	Confirmatory test
Motor delay	<ul style="list-style-type: none"> <li>• Developmental observation card (DOC; 1 month to 1 year)</li> <li>• Trivandrum developmental screening chart (TDSC; 1–2 years)</li> <li>• Denver developmental screening test (DDST; 1–6 years)</li> </ul>	<ul style="list-style-type: none"> <li>• Developmental assessment scale for Indian infants (DASII)</li> <li>• Clinical adaptive test (CAT)</li> </ul>
Early language delay	<ul style="list-style-type: none"> <li>• TDSC</li> <li>• DDST</li> <li>• Early language milestone (ELM) scale</li> </ul>	<ul style="list-style-type: none"> <li>• Clinical linguistic and auditory milestone scale (CLAMS)</li> <li>• Receptive and expressive emergent language scale (REELS)</li> </ul>
Cognitive or adaptive delay	<ul style="list-style-type: none"> <li>• TDSC</li> <li>• DDST</li> <li>• Parents evaluation of developmental status (PEDS)</li> </ul>	<ul style="list-style-type: none"> <li>• DASII</li> <li>• Seguin Form Board (SFB)</li> <li>• Raval-Vineland Social Maturity Scale (&gt; 2 years)</li> </ul>

in presence of microcephaly, hepatosplenomegaly, petechial rash, jaundice and chorioretinitis.

Biochemical tests are indicated in children suspected to have amino acidopathy, organic aciduria, galactosemia, phenylketonuria, homocystinuria, urea cycle defects, mitochondrial disorders

and mucopolysaccharidoses. The confirmatory tests for these disorders include enzyme studies in lymphocytes, fibroblasts and other tissues.

## MANAGEMENT

Multidisciplinary consultation is needed for a comprehensive evaluation and management of children with GDD. The aim being goal-driven, therapeutic interventions act as a conduit to long-term community-based rehabilitation and educational resources. Multiple allied health services, such as physical therapy for gross motor, locomotion and balance; occupational therapy for fine motor, activities of daily living (ADL), feeding; speech and languages pathologists for speech therapy and psychologists for cognition, social and behavioral issues are required.

### Early Intervention

Development of the brain continues postnatally and is influenced by extrinsic environmental factors as well as *preprogrammed* genetic factors. Postnatal growth continues into adulthood but it is most rapid and pliable during first few years of life. An outcome of a developmentally delayed child can be improved by modifying the environment. Neuroplasticity is the primary principle for the early intervention program. Neuroplasticity refers to the changes that occur in the organization of the brain as a result of experience. The reorganization is done via the mechanism of axonal sprouting. Therefore, earlier the intervention, better will be the outcome. This is the main principle of early intervention therapy.

The intervention team consists of medical specialists and the rehabilitative team wherein preliminary developmental tests are performed to establish the diagnosis. Early intervention therapy with a home-based program—is more beneficial if started in the first few months of the life, especially less than 6 months. The stimulation is done in areas of visual, tactile, auditory, sensory, head movement, head holding and babbling. Specific management should focus on nursing, feeding and positioning of the child. Antispasticity medications, antiepileptic drugs, orthosis, splints, corrective surgeries, assistive technologic devices should be considered based on needs of the individual child. Rehabilitative services are provided as individual, group or as a home-based program.

Physical therapists use isometric exercises for strengthening, flexibility of muscles and increasing the range of movements. Gait training and bracing is done to improve locomotion and posture maintenance. Occupational therapy consists of developmental therapy and functional therapy for ADL skills.

### Neurodevelopmental Therapy

It originated from Bobath and Bobath in 1940s. The *Classic* neurodevelopmental therapy (NDT) was based on the principle that the CNS dysfunction is the primary cause of movement, posture and development. The normal development was promoted through strict adherence to a normal development sequence and was originally developed for children with cerebral palsy. The contemporary NDT focuses on functional tasks and skills with the normal developmental sequence used as a general guide and less relied upon. It has a broader focus, with CNS as only one of the many systems that impact movement and development.

### Sensory Integrative Treatment

It is based on the premise that the brain processes internal and external sensory information and organizes it for an appropriate response. Deficits in the ability to integrate sensory information can be remediated with guided sensory inputs to elicit an adaptive response such as proprioceptive, tactile, and vestibular stimuli.

The other interventional approaches include aquatic therapy, cognitive orientation to daily occupational performance, constraint to induced movement therapy, hippotherapy and others.

## IN A NUTSHELL

1. Global developmental delay refers to a significant delay in two or more developmental domains in young children under 5 years of age.
2. Prevalence of GDD varies from 2.5% to 10% as reported in different studies in the world.
3. The etiology of GDD includes a wide spectrum of genetic, prenatal, perinatal and postnatal factors. However, in a significant number of cases exact etiology cannot be established.
4. In India, perinatal causes remain major etiological diagnosis in majority of children with GDD.
5. Evaluation of a child with GDD includes detail history-taking, observing the baby in a child-friendly environment, and conducting accurate general physical and neurodevelopmental examination. Team of several health professionals is essential to ensure a complete and thorough evaluation.
6. Neurodevelopmental assessment is essential in all children with GDD. Vision and hearing is mandatory in each case. Various screening and confirmatory tests are now available in India.
7. Laboratory tests include neuroimaging, hormonal tests, cytogenetic studies, bacteriological and microbiological tests for infectious causes and tests for metabolic disorders. Laboratory test should be carefully selected, based on history and clinical examination.
8. Management of a child with GDD includes early intervention therapy, behavioral therapy and counseling of the family regarding diagnosis, risk of recurrence, and possible outcome. Specific pharmacotherapy may be indicated in some children having GDD with neurological disorder.

## Chapter 20.5

# Intellectual Disability

Suja Koshy

Intellectual disability (ID) is the most common developmental disorder with deficits in cognitive functioning (IQ < 70) and adaptive skills originating before the age of 18 years. Children with intellectual disabilities are below average in intelligence, have limitations in their intellectual functioning and also have difficulties in coping up with the challenges associated with daily life, i.e., to communicate, socialize or take care of their everyday needs.

It includes a heterogeneous group of conditions ranging from *children with severe developmental disabilities* who need constant support to *children with only mild delays*. Though ID is different from global developmental delay (GDD), GDD is often a precursor to ID. GDD is the term applied to age less than 5 years; significant delay (performance two standard deviations or more below the mean on age-appropriate, standardized norm-referenced testing) in two or more of developmental domains including gross/fine motor skills, speech/language, cognition, social/personal, activities of daily living (ADL). *Intellectual disability* is a term applied to age more than or equal to 5 years and manifesting before age 18 years, historically referred to as *mental retardation*; intellectual functioning level (IQ) less than 70–75 and significant limitations in two or more adaptive skills.

There is no single characteristic feature, prognosis or cause for ID. The medical model looked upon intellectual deficit as an illness, but today the educational model looks upon it as a developmental disability where there is new emphasis on the rights of the child. Today, ID is not considered a static disorder, but a dynamic condition dependent on the etiology and available environmental supports.

### TERMINOLOGY

Though the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) has replaced *mental retardation* with *intellectual disability* (intellectual developmental disorder), as of 2014, the old term is still used by the World Health Organization (WHO) in the International Classification of Diseases (ICD)-10 codes. "A condition of arrested or incomplete development of the mind, which is especially characterized by impairment of skills manifested during the developmental period, skills which contribute to the overall level of intelligence, i.e., cognitive, language, motor and social abilities. Retardation can occur with or without any other mental or physical condition." [Source: Chapter V, *Mental and behavioral disorders (F00-F99)*, p. 176 *The ICD-10 Classification of Mental and Behavioral Disorders, Clinical descriptions and diagnostic guidelines*. WHO, 1996. Reprinted with permission] In the next revision, the ICD-11 is expected to replace the term *mental retardation* with *intellectual disability*. Unfortunately, the term *mental retardation* is still used sometimes in professional medical settings in India and some parts of the world.

### DEFINITION

Different definitions of the term; intellectual disabilities' have been accepted professionally. In India, *mental retardation* means a "condition of arrested or incomplete development of mind which is specially characterized by subnormality of intelligence" as per

the Persons with Disabilities (Equal Opportunities, Protection of Rights and Full Participation) Act, 1995. No doubt, the use of the term *mental retardation* is still in use in India and the content of the definition really points to the long overdue need for reviewing this definition.

The widespread definitions used are given by the American Association on Intellectual Developmental Disabilities (AAIDD), IDEA, WHO and the American Psychological Association (APA). The definition as given by IDEA is "significantly subaverage general intellectual functioning existing concurrently with deficits in adaptive behavior and manifested during developmental period, that adversely affects a child's educational performance". (Source: *National Dissemination Center for Children with Disabilities, NICHCY*)

The AAIDD definition (2010) of intellectual disability is "a disability characterized by significant limitations in both intellectual functioning and in adaptive behavior, which covers many everyday social and practical skills. This disability originates before the age of 18." (Source: *Schalock et al, 2010*).

Hence, it can be seen that through the years, disagreement was seen with respect to the definitions of intellectual disabilities. Some definitions relied on:

- IQ scores alone to classify individuals with intellectual disability,
- only adaptive behaviors for classification and
- both IQ scores and measures of adaptive behavior.

But today, there is more consensus and the common elements of the definitions are:

- The onset period of intellectual disabilities as being the developmental period (i.e., before 18 years)
- Impairments evident in both cognitive functioning and adaptive skills.

The DSM-5 definition focuses toward identifying limitations, whereas the AAIDD (2010) focuses on detecting current abilities and strengths of individual that facilitate rehabilitation. AAIDD stresses that additional factors must be taken into account, such as the community environment, linguistic diversity, cultural differences typical of the individual's peers and culture while defining and assessing ID.

Due to the paradigm shift from the medical model to the educational model, professionals have realized the need to have more effective systems of identification and classification for providing more effective educational and rehabilitative interventions to children with intellectual disabilities.

### CLASSIFICATION OF INTELLECTUAL DISABILITIES

Intellectual disabilities exist along a continuum with the degree varying from person to person, and it can be classified as mild, moderate, severe or profound. Looking from the clinical perspective, the two major categories of intellectual disabilities are as follows:

1. Syndromic, characterized by associated clinical, radiological, metabolic or biological features
2. Nonsyndromic forms of ID in which the cognitive impairment represents the only manifestation of the disease.

The boundaries between the syndromic and nonsyndromic forms are not very stringent, as in both these types there is association of several genes.

The other major ways of categorizing groups of ID are as:

- metabolic syndromes,
- syndromes with ID and
- associated malformations/dysmorphism and syndromes with ID and neurological/neuromuscular symptoms.

From the educational perspective, there has been a paradigm shift in the way children with intellectual disabilities are classified. The ICD-10 is the most widely used classification system across all member countries of the WHO 2007 (**Fig. 1**). But unfortunately, the IQ-based classifications are not helpful for intervention planning. Presently rather than emphasizing IQ-based subgroups (mild, moderate, severe and profound), professionals are encouraged to describe needed *appropriate supports* to improve adaptive functioning for individuals with ID (**Table 1**). The various levels of severity are defined on the basis of adaptive functioning rather than IQ scores, because the adaptive functioning determines the patterns and level of supports required (i.e., intermittent for mild, limited for moderate, extensive for severe and pervasive for profound). Moreover, IQ measures are less valid in the lower end of the IQ range. However, others opine that to provide appropriate services, it is vital to emphasize the child's capacity level (intellectually and adaptively).

## EPIDEMIOLOGY

Intellectual disability prevalence rates vary according to the definitions and classification system being used. Worldwide prevalence of ID is approximately between 2.5% and 3% of the general population. Other specialists argue that the prevalence is lower as ID is not only determined by the child's individual IQ score alone, and the adaptive functioning may not be impaired (as many children with 50–70 IQ scores may not show significant deficits in adaptive functioning). In India, no reliable prevalence data is available due to lack of national level population-based study. Small epidemiological studies in India indicate 2–3% of our population of children have ID, i.e., 1 in 800 livebirths. However, a wide discrepancy in incidence of ID has been reported, from around 1/1000 to 32/1000. Among those with a diagnosis of ID, mild ID affects about 85% of the population, moderate ID about 10%, severe ID about 4%, and profound

ID about 2%. About 0.5% children are severely intellectually disabled due to etiological medical causes. Additionally, there are 1.6 children with Down's syndrome per thousand newborns. The incidence of congenital hypothyroidism (CH) is quite high with 1 in 1000 cases.

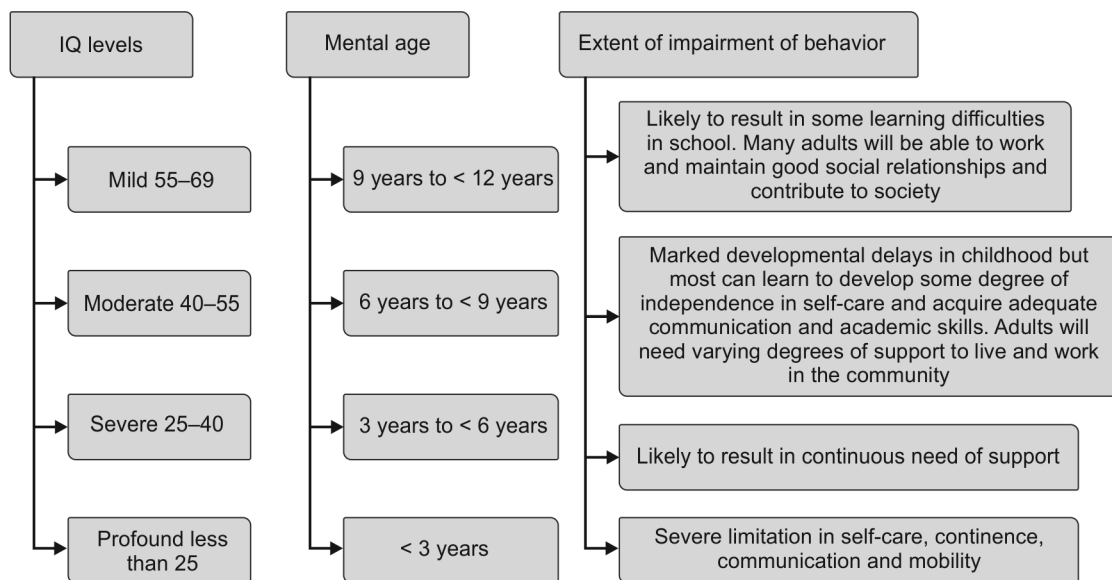

The proportions of ID have been reported to be higher in males, especially in mildly intellectually disabled individuals. This could be due to more incidences of congenital anomalies and more premature births in boys. Another reason is the presence of X-linked forms of ID. The prevalence of males to females is 2:1 in intellectual disabilities necessitating intermittent supports and 1.2:1 in intellectual disabilities needing extensive supports, due to sex-linked disorders like fragile X syndrome. The prevalence peaks at 10–14 years of age as children with intellectual disabilities requiring intermittent supports are identified considerably later than those with more severe impairments.

The prevalence of emotional, behavioral and psychiatric disorders is three- to fourfold greater in persons with ID.

## ETIOLOGY

There are innumerable causes of intellectual disabilities, and determining the exact cause of ID is very difficult. The causes are more understood in more than 70% of children with severe intellectual disabilities, whereas causes in 40–50% cases remain idiopathic. In two-third of the cases of mild ID and one-third of the cases of severe ID, no causes are found.

The causes can be diverse from *genetic and metabolic disorders* to trauma to brain at birth or at later ages. A child can develop ID due to prenatal, perinatal or postnatal causes (**Table 2**). Perinatal causes have been found to be the most common cause of ID. Of these, genetic factors play an important role in the etiology of 30–50% cases of ID. Chromosomal abnormalities like Down's syndrome and fragile X syndrome are the most diagnosable genetic causes of ID.

**Figure 1** Classification of severity of intellectual disability

**Table 1** Intellectual disability (ID) and adaptive functioning

Definition	Adaptive skills are defined as practical, everyday skills needed to function and meet the demands of one's environment, including the skills necessary to effectively and independently take care of oneself and to interact with other people.				
Domains	Conceptual language, functional academics, telling time, ability to learn and remember information Social—interpersonal skills, following rules (turn-taking during games), social-problem solving, empathy, making friends Practical—personal self-care, home-living, health and safety, recreational activities, occupational skills.				
Assessment of adaptive behavior	Standardized adaptive rating scales Semi-structured clinical interviews Observation at home/school				
Adaptive behavior at each level of severity of ID		Mild ID (85%)	Moderate ID	Severe ID	Profound ID
Conceptual	Ability to think, learn and remember	Concrete thinking. Lacks abstract thinking. Inability to generalize	Inability to think logically	Limited ability	Visual-spatial skill at concrete level present
	Reading, writing, counting, solving Maths problems	Difficulty in coping with academics. Requires more time and practice to master academics Can generally learn reading, writing and math skills between the 3rd and 6th standard levels.	Can achieve preacademic skills at slow pace. Unlikely to go beyond 2nd standard level Academics	No understanding of written language. Unable to read or write. Functional academics not readily developed	Functional academics not readily developed
	Understanding language and speaking	Concrete and immature language	Simplistic usage of grammar	Difficulty pronouncing words. Limited vocabulary Understands simple language and gestures	Likely to have little or no speech, and will rely on gestures, facial expression
Social	Interpersonal skills	Difficulty in developing and keeping friends. Immature social judgement. Gullible	Generally rejected. No age-appropriate social skills	Extremely isolated. Relationships with family/familiar people	Relationships with family
	Understanding others	Difficulty in understanding social cues	Limited social understanding	Social understanding significantly impaired	Social understanding significantly impaired
Practical	Self-help skills	Age-appropriate skills in childhood. Look after themselves	Needs assistance (extended instruction) in caring for self	May lack self-help skills	Needs 24-hour care and support for self-care
	House work	Performs house work (shopping, money) with additional time, instructions and reminders	Chores left half done	Performs simple tasks in closely supervised settings	Some can perform simple tasks in closely supervised and sheltered settings
	Travel	With guided instructions, can use transportation reasonably well	Can learn to use public transport to travel to familiar places	Restricted to home	Restricted to home
	Occupational skills	Performs semi-skilled jobs	Can do semi- or unskilled jobs. Faces difficulty at workplace	Not employable	Homebound

There is an evidence also that various *environmental factors* contribute to ID. Recent research has revealed that the causes in India are mainly due to:

- Serious postnatal infections like encephalitis and meningitis during childhood
- Malnutrition (micronutrient deficiencies)
- Illness during pregnancy and birth-related causes (4%). The most common perinatal cause is neonatal complications due to anoxia, premature birth or low birthweight
- Serious illnesses during childhood (48.6%)
- Serious lead-poisoning and other toxic exposures can cause serious cerebral damage, which is irreversible
- Grave head injuries (falling from table, open window, balcony and stairs) can lead to cognitive impairments
- Environmental neglect and physical trauma in children who are physically abused can also cause cognitive impairments
- In many cases, the cause is unknown (22.4%).

## **PATHOGENESIS**

No specific neuropathologic correlates of ID have been documented. It occurs due to mutations in single genes that code for enzymes which results in abnormal or reduced enzyme activity. It is accepted that ID can stem from two broad mechanistic themes: dysfunction of neurodevelopmental programs and alterations in synaptic organization and plasticity.

One to five percent of nonsyndromic ID are inborn errors of metabolism. The most common inborn error of metabolism associated with ID is phenylketonuria (PKU) which has an average worldwide estimated prevalence of 1:10,000. The most common single chromosomal cause of ID is Down's syndrome. The most common form of X-linked intellectual disability, fragile X syndrome has prevalence of approximately 1:2,500 individuals. Children with Prader-Willi syndrome and Angelman syndrome also have ID.

**Table 2** Causes of intellectual disabilities

Prenatal	Chromosomal disorders	<ul style="list-style-type: none"> <li>• Down syndrome (Trisomy)</li> <li>• Fragile X-syndrome</li> <li>• Prader-Willi syndrome</li> <li>• Angelman syndrome</li> <li>• Williams syndrome</li> </ul>
	Inborn errors of metabolism	<ul style="list-style-type: none"> <li>• Phenylketonuria</li> <li>• Galactosemia (carbohydrate disorder)</li> </ul>
	Developmental disorders of brain formation brain formation	<ul style="list-style-type: none"> <li>• Hydrocephalus</li> <li>• Idiopathic microcephaly</li> <li>• Spinal bifida</li> </ul>
	Maternal illness	<ul style="list-style-type: none"> <li>• Rubella</li> <li>• HIV</li> <li>• Diabetes mellitus</li> <li>• Hypothyroidism</li> </ul>
	Embryonic teratogen exposure	<ul style="list-style-type: none"> <li>• Maternal substance use</li> <li>• Fetal alcohol syndrome</li> </ul>
	Acute placental insufficiency	<ul style="list-style-type: none"> <li>• Toxemia/eclampsia</li> <li>• Placenta hemorrhage</li> </ul>
	Chronic placenta insufficiency	<ul style="list-style-type: none"> <li>• Maternal diabetes</li> <li>• Erythroblastosis</li> </ul>
	Difficult or complicated delivery (Intrauterine disorders)	<ul style="list-style-type: none"> <li>• Prematurity</li> <li>• Breech</li> <li>• Multiple gestation</li> <li>• Obstetrical trauma</li> </ul>
Perinatal	Neonatal complications	<ul style="list-style-type: none"> <li>• Anoxia</li> <li>• Septicemia</li> <li>• Severe jaundice</li> <li>• Hypoglycemia</li> </ul>
	Head injuries Infections	<ul style="list-style-type: none"> <li>• Falls and accidents</li> <li>• Encephalitis</li> <li>• Meningitis</li> <li>• Measles</li> <li>• Rubella</li> </ul>
Postnatal	Degenerative disorders Seizures Toxic-metabolic disorders Severe and prolonged malnutrition Environmental deprivation	<ul style="list-style-type: none"> <li>• Rett syndrome</li> <li>• Infantile spasms</li> <li>• Chronic exposures to lead/mercury</li> <li>• Protein-calorie (Kwashiorkor, marasmus)</li> <li>• Child abuse and neglect</li> </ul>

During development, neurogenesis and cell migration occur in a tightly controlled spatiotemporal manner, during which neurons form intricate axonal and dendritic connections. Small disruptions in any of these processes during development can lead to cognitive dysfunction in children.

Defects in the control of neuronal number, from excess or defects in germinal epithelial proliferation can lead to disorders. Microcephaly is known to be associated with mutations in at least 4 genes (*MCPH1*, *ASPM*, *CDK5RAP2* and *CENPF*), all associated with cell division and cell cycle regulation.

## CLINICAL FEATURES

The presenting signs and symptoms may vary as per the level and the etiology of ID and include delay in language, cognitive skills and adaptive skills. The signs for severe and profound level of ID may be obvious from birth itself, whereas for mild degree of ID, it may be noticeable only by 3–4 years.

**Language delay** Most common clinical presentation in these children is delay in receptive and expressive language. Developmental history might reveal that the infant did not babble till 12 months, or at 2 years has still not spoken anything, and may

have started speaking between 3 and 6 years. Expressive language even at 12 years may be limited to simple two- to three-word sentences. Some parents may show apprehensions about the child being hearing impaired.

**Fine motor/adaptive delay** Noteworthy delay noticeable in ADL, such as toileting and self-feeding. Drooling may be observed even at the time of physical examination. Parents might complain of child being messy while eating.

**Gross-motor delays** Slight delays in gross-motor development are seen. Oro-motor disorders (drooling) seen more in children with moderate, severe and profound levels of intellectual disabilities. The child with ID may be clumsy with poor motor co-ordination.

**Neurologic and physical abnormalities** About 25–30% of children with intellectual disabilities develop epilepsy by childhood. Indian studies reveal that high proportions of children with ID have had history of neonatal seizures.

**Associated behavioral manifestations** Complaints of difficult temperaments, irregular sleep habits, hyperactivity may

come up in the history-taking. The children with intellectual disabilities requiring extensive supports often have associated impairments like 10% are hearing impaired, 20–25% are visually impaired, 33% have seizure disorders, 30–60% of children with severe intellectual disability have cerebral palsy, 4–18% have a co-occurring psychiatric disorder like schizophrenia, depressive disorder, phobic disorder or generalized anxiety disorder. Communication impairments and ADHD are some associated problems related to severe ID. A number of children with ID are persistently overactive, impulsive and distractible with short attention span. Respiratory diseases are a leading cause of early deaths in children with ID due to problems of posture, feeding and swallowing. These associated impairments may create dilemma in differentiating ID from other developmental disabilities.

A tall stature may suggest fragile X syndrome, whereas short stature may suggest a genetic disorder, fetal alcohol syndrome or hypothyroidism. A short stature along with some of the characteristics (flat broad face, oval-shaped eyes, flattened nasal bridge, brachycephaly, small oral cavity with short roof and protruding tongue, epicanthic folds, upward sloping palpebral fissures, redundant loose neck skin, single palmar crease, wide gap between first and second toes, fifth finger clinodactyly) may indicate the possibility of the child having Down's syndrome. Common features of children with fetal alcohol syndrome include growth deficiency, widely spaced eyes with narrow eyelids, long smooth philtrum, thin upper lip, short nose, epicanthal folds, small head circumference, underdeveloped jaws with malocclusion, hyperactivity and attention problems.

## DIFFERENTIAL DIAGNOSIS

The conditions that could be mistaken for intellectual disabilities are listed in **Box 1**. Though a child with cerebral palsy also may show average to severe impairment in areas of motor development and expressive language, there is generally no cognitive limitation in a child with cerebral palsy. Similarly, a child with communication disorder shows severe delay in expressive and receptive language without major cognitive limitation.

Children should be referred for a hearing and vision test to rule out problems of hearing and vision. Approximately one-fourth of the children with isolated ASD have an occipitofrontal circumference greater than the 97th percentile which becomes apparent by 3–4 years. A full evaluation of the child will help sort this out. At times, repeated evaluations may be needed to determine the primary developmental disability.

When a school age child is referred, the presenting problem may be poor academic performance. In such situations, the differential diagnosis should include problems like ADHD, learning disabilities and language disorders.

Hearing problems, specific language problems and Autism spectrum disorders may be confused with ID in young children, or may coexist with ID.

### BOX 1 Differential diagnosis of intellectual disability

- Autism spectrum disorder
- Child with hearing impairment
- Cerebral palsy
- Communication disorder
- Child with borderline intellectual functioning
- Child with learning disabilities
- Specific language problems
- Child with cultural deprivation/lack of stimulation.

## MAKING THE DIAGNOSIS

Intellectual disability could be suspected in children significantly below the normative developmental milestones for their age. Today, the diagnosis of ID is based on three main criteria: (1) significant subaverage general intellectual functioning; (2) limitations in adaptive behavior in at least two of the following skills: communication, self-care, home living, social/interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and (3) onset of the symptoms before 18 years of age. A large percentage of children diagnosed with GDD may eventually meet the diagnosis of ID. Among the professional organizations, there is a consensus that accurate diagnosis of intellectual disability requires clinical judgment based on comprehensive three basic criteria:

1. Evidence of general low intellectual functioning level (approximately two standard deviations or more below the mean as compared to children of their own age) measured by standardized intelligence tests;
2. Concurrent deficits/impairments in adaptive functioning in at least two of the following areas, (communication, self-care, home living, social/interpersonal skills, functional academic areas, leisure, health and safety; and
3. Onset is before the age of 18 years for both intellectual and adaptive deficits (**Table 3**).

Goal of diagnosis should not be to *label* or finding the cause, but to identify strengths and plan intervention and provide optimal support to the child (**Fig. 2**). An intelligence test alone cannot diagnose intellectual disabilities in children. Child should also have a testing in adaptive behavior. Child with IQ score of above 70 may still have severe problems in other areas of functioning. Early diagnosis by the pediatrician can provide the opportunity for early referral for intervention.

## Developmental Screening

The aim of developmental screening tool is to identify children who need more comprehensive evaluation. Unfortunately, developmental screening tools are not widely used in pediatric practice as it is time-consuming with no monetary benefit. After developing rapport with the child and making the child comfortable, a thorough physical examination can be done (with accurate measurements of growth parameters, including head circumference). Assess the functioning of vision, hearing and motor function. Look for any dysmorphism and congenital anomalies. This should be followed by a complete neurodevelopmental assessment.

It is prudent for the pediatrician to become familiar with some of the following developmental screening tests which were discussed in Chapter 20.3.

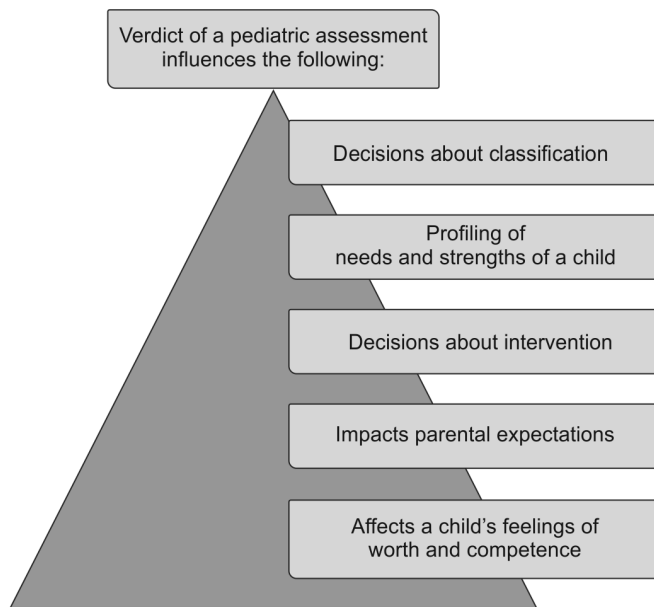

- Denver Developmental Screening Test: Denver II (DDST-II, 1992) (Revised)
- Neonatal Behavioral Assessment Scale, Brazelton (NBAS or BNBAS)
- Bayley Scales of Infant Development (Bayley-III) (BSID, Bayley 1993)
- Developmental Assessment Scales for Indian Infants (also referred to as Phatak's Baroda Screening Test) 2nd Edition (DASI-II, 1997)
- Trivandrum Development Screening Chart (TDSC) (0–6 years), 2013

Amiel-Tison and Hammersmith neonatal neurological screener are tests that can predict neurodevelopmental disability. Amiel-Tison test is comparable to BSID and is useful for motor developmental disability. Hammersmith neonatal neurological screener is a simple test which assesses the baby's reflexes,

**Table 3** Intellectual functioning and adaptive behavior

Intellectual functioning	Adaptive behavior
<p><b>Intellectual functioning</b>—also called intelligence—refers to general mental capacity, such as learning, reasoning, problem-solving, and so on</p> <p>One way to measure intellectual functioning is an IQ test. Generally, an IQ test score of around 70 or as high as 75 indicates a limitation in intellectual functioning</p>	<p><b>Adaptive behavior:</b> Adaptive behavior is the collection of conceptual, social and practical skills that are learned and performed by people in their everyday lives</p> <p><i>Conceptual skills:</i> Language and literacy; money, time and number concepts, and self-direction</p> <p><i>Social skills:</i> Interpersonal skills, social responsibility, self-esteem, gullibility, naivete (i.e., wariness), social problem-solving, and the ability to follow rules/obey laws and to avoid being victimized</p> <p><i>Practical skills:</i> Activities of daily living (personal care), occupational skills, healthcare, travel/transportation, schedules/routines, safety, use of money, use of telephone</p>

**Figure 2** Assessment of a child with intellectual disability

movements, posture and tone, movement, orientation/behavior and abnormal patterns. It can be administered easily in an OPD ward. If two items are in the shaded areas, the neonate should be sent for detailed evaluation.

Check for coordination of the child while the infant reaches out to toys, etc. Unusual muscle movements like spasmus nutans (periodic head nodding, occasional abnormal positioning of the neck) is sometimes seen in decreased IQ. If diffuse or focal abnormalities are seen in the detailed neurological screening, then it indicates the need for neuroimaging.

### Developmental Surveillance

Today, developmental surveillance is replacing the concept of developmental screening. *Developmental surveillance*, an important function of the pediatrician, is a flexible, continuous process which includes eliciting and attending to parental concerns, obtaining relevant developmental history, making accurate observations, record keeping of surveillance and sharing concerns with multidisciplinary team. Utilize the immunization contact days or follow-up appointments for developmental surveillance. In 2013, Indian Government launched the *Rashtriya*

*Bal Suraksha Karyakram* (RBSK) aimed at screening over 270 million children from 0 to 18 years for four Ds: Defects at birth, Diseases, Deficiencies and Development Delays including Disabilities.

Pediatricians should increase interaction with the parents so as to listen actively regarding the children's development, which will help them to gain more insight into the behavioral indicators.

- Studies indicate that parental apprehensions about the child's development are highly predictive of true problems. For example, delay in motor milestones and speech delay are developmental concerns which may be voiced by parents during the early years.
- Concerns taken casually by the pediatrician can lead to substantial delay in early diagnosis.
- Recently screening tools have been developed that respond to parental concerns. By using these tools, parents become active participants in the care of their child.
- In the West, use of *parents' evaluation of developmental status* (PEDS) has been recommended for screening of all children. The parent is asked questions to elicit their concerns. For example, the pediatrician may say "Please tell me any concern about your child with regard to learning, development and behavior" or "Do you have any concern about how your child uses his hands and fingers to do things?" The responses given by the parents are then categorized into significant and nonsignificant concerns (depending on the developmental domain and age of the child) as per the guidelines of PEDS.

However, in India, a very different situation prevails. Some uneducated parents believe that the doctor is the enlightened one who guides the parents and hence may not raise any concerns from their side. At other times, parental concerns are ignored or not given enough weightage by some professionals. Indian research reveals that PEDS is not an alternative to standardized developmental testing.

### INVESTIGATIONS

#### Laboratory Tests

Genetic testing has evolved greatly, but a judicious choice of most useful and cost-effective tests has to be made. When laboratory tests are advised, counsel the family patiently and appropriately about possible outcomes of the tests. As compared to standard karyotyping and fluorescence in situ hybridization (FISH) assays, chromosomal arrays are highest yielding tools where the cause is unknown. The two common types of arrays are comparative genomic hybridization (CGH) and single-

nucleotide polymorphism (SNP). G-banded karyotyping detects in 2–4% of cases, FISH in 2.4–3.5%, and CGH and SNP has yield of 10–30%.

## Neuroimaging

Neuroimaging is recommended for children with abnormal head growth. Magnetic resonance imaging (MRI) is more sensitive than CT scans in detecting brain abnormalities related to developmental delays due to intracranial pathology and structural abnormalities. Electroencephalography (EEG) can be recommended for seizure disorders. Brain scans of children with fragile X show abnormalities of the prefrontal cortex, caudate nucleus and cerebellum.

## Metabolic Testing

Blood and urine tests are done in suspected cases, especially when there is a family history of ID. Urine tests recommended for PKU for early diagnosis, which in turn helps the newborn to grow up with normal brain development. A *musty odor* of the baby's sweat and urine (due to presence of phenyl acetate), is one of the prominent signs of the presence of PKU.

## TESTS OF INTELLIGENCE AND ADAPTIVE SKILLS

The multidisciplinary assessment approach to ID should also include a battery of intelligence tests to assess a child's ability to think abstractly, learn and solve problems. A child may have ID if the IQ test results are 70 or below. It is vital to recognize the cultural implications while doing intelligence testing.

### Commonly used Definitive IQ and Social Maturity Tests

*Wechsler Intelligence Scale for Children*® (WISC®-IV, 2003) (6 years and 16) WISC scores yield an overall intelligence quotient, called the full scale IQ. The main advantage of this test is a separate verbal and performance IQ.

*Wechsler Intelligence Scale for Children*® Fifth Edition (WISC®-V) (age range: children aged 6:0–16:11, paper-pencil and digital format).

*Wechsler's Intelligence Scale for Children*® (WISC®) *Indian Adaptation*, AJ Malin, (5–15 years) Test similar to original version of WISC but adapted to Indian child.

*Stanford Binet-Kamat test of intelligence* (3–22 years) Includes items related to vocabulary, language development, sentence building, similarities and differences, analogies, sentence repetition, auditory perception and visuospatial coordination ability.

*Bhatia's battery of performance test* This is frequently used with children (even the semiliterate and hearing impaired). It consists of five subtests: Koh's block design, Alexander's pass-along test, pattern drawing, digit span and picture construction test.

*Seguin Form Board* A nonverbal test for assessing the eye-hand co-ordination, shape concept, visual perception and cognitive ability. It is given to children from birth to 5 years and takes about 20 minutes to administer.

*Raval's Vineland Social Maturity Scale* (birth to 15 years) Measures the adaptive skills of children from 1 year to 15 years. The information is collected from the parents/caregivers who are familiar with the behavior of the child. The domains assessed by this scale are communication (receptive, expressive and written), socialization (interpersonal relationships, play and leisure time, coping skills), and motor skills. Scoring is not as easy as the original test and few items are culturally irrelevant. The scale yields

a social age which can be converted to a *social quotient* (SQ) score calculated as follows:

$$SQ = \frac{\text{Social Age}}{\text{Actual Age}} \times 100$$

## Tests of Adaptive Functioning

Diagnostic and Statistical Manual of Mental Disorders and ICD-10 indicate that adaptive skills need to be measured in addition to IQ testing.

*Vineland Adaptive Behavior Scales* (VABS) (birth to age 90): The most widely used instrument is the VABS, 2nd Edition (Sparrow, Cicchetti, and Balla, 2005). Adaptive functioning is measured in four domains (*communication, daily living skills, socialization and motor skills*). It gives the adaptive behavior composite score and the maladaptive behavior domain.

The different degrees of intellectual disability which are diagnosed are generally diagnosed at different ages of growth. For example, mild intellectual disability is generally diagnosed in school years through deficits shown while processing novel or complex information in academic tasks; while moderate intellectual disability may be diagnosed by 3–4 years through cognitive/social adaptive/language deficits. Severe intellectual disability can be easily diagnosed by one year through the dysmorphic features associated with medical conditions, low Apgar scores, poor feeding, hypoglycemia, hypothermia and presence of seizures.

## MANAGEMENT

### Sharing the Diagnosis and Psychoeducation

*Sharing of diagnosis* with the parent is a skill that a pediatrician needs to develop.

- Break the news to parents about the condition as promptly as possible after the diagnosis.
- Assign sufficient time for this session as families will always recall the way in which they were informed of their child's diagnosis.
- Counsel the parents together with sensitivity, empathy and present information, in an uninterrupted and non-rushed manner.
- Help to educate parents about intellectual disabilities as it empowers them to become advocates for the child in the society.
- Explain the diagnosis in simple helpful language to the parents, emphasizing the prognosis. They need to be told it is incurable and clarify the term *developmental delay*, as parents frequently misinterpret this as meaning the child has the ability to catch up.
- Ample time should be scheduled to discuss the findings and to allow for questions, which will be numerous. The family should be encouraged to write a list of questions for further communication with the physician.
- Enlighten families regarding the intervention and management options available. Guide them to seek early intervention after screening and assessment.
- All through this interaction, it is important to help the parents talk about their own feelings.

### Planning for the Intervention

Development of a comprehensive intervention plan is essential with inputs from multidisciplinary team of professionals (special educators, speech therapist, and occupational therapist) as many of the children with intellectual disabilities also have associated problems. This plan is called the individualized support plan (ISP)

or individualized therapy plan (ITP) which maximizes functioning through the strength model. All through the intervention, the child should be the center/focus with the professionals coming in or going out as per the needs of the child. AAIDD definition of ID is more often used toward identifying abilities which in turn facilitates rehabilitation.

### Early Intervention

Early intervention is crucial and it includes infant stimulation, speech and language therapy, physiotherapy, occupational therapy, parent counseling and training. A developmental model focuses on early, continuous intervention along with positive supports. Early intervention helps to alter the developmental trajectories by minimizing secondary complications.

Though the medical doctor is the first person usually to disclose the ID in young children, most do not refer these children for early intervention. Explaining about early intervention gives reassurance to the parents. National Institute for the Mentally Handicapped (NIMH) has exclusive units for early intervention and parent training.

### Functional Assessment

The importance of assessment for teaching by the teacher has come to the focus in India in recent years. An informal functional assessment guide for all disabilities has been developed (NCERT, 1990) for use by teachers. In addition, educational assessment tools for these children, such as Madras Developmental Programming System (MDPS, 1991), an adaptation of Minnesota Developmental Programming System, Indian adaptation of Portage Guide to Early Education (1987) and Functional Assessment Checklists (1994) by NIMH are popularly in use in India. Another assessment scale developed by NIMH is called *behavioral assessment scale* for Indian children with MR which is available for making objective assessment for planning training programs. The linguistic, sociocultural practices vary from region to region in India and there is a trend in various states to develop functional assessment tools suitable to their region. Finally, assessments must also assume that limitations in individuals often coexist with strengths, and that a person's level of life functioning will improve if appropriate personalized supports are provided over a sustained period.

The Functional Assessment Checklists (NIMH) have the items described in terms of activities rather than skills for early monitoring. Periodic quarterly assessment provision is made and the checklists are separately developed for children from pre-primary to prevocational levels (age range of 3–18 years). Separate checklist for profoundly intellectually disabled children in the name of care group is provided for these children.

### Educational Placement

Guide the parents to select the appropriate educational interventions. Brochures giving information about a list of centers/schools, and support groups could be distributed to the families. Educational facilities in India range from special schools to inclusive schools. A central issue in intervention of these children is whether they should be placed in special schools or for inclusive education in regular schools and provided additional supports. This decision will depend on the individual needs of the student.

A significant objective of these schools is to provide education for adaptive functioning. Adaptive behavior is referred to as the effectiveness with which the individual copes with the nature and social demands of the environment. These children need help with skills needed to live, work, and play in the community. Teachers

and parents can help a child work on these skills at both school and home. Training needs to be provided in the following areas:

- Taking care of personal needs (dressing, bathing, going to the bathroom)
- Health and safety
- Home living (helping to set the table, cleaning the house, or cooking dinner)
- Communicating and interacting with others
- Social skills (manners, getting along in a group, playing a game)
- Reading, writing and basic math
- As they get older, skills that will help them in the workplace.

### Vocational Training

Never underestimate the abilities of children with intellectual disabilities. Though many may need constant medical care and support, many can also function independently as adults. Develop the vocational skills of the youth with intellectual disabilities so as to increase their employability. Let them work in sheltered workshops or under supervision. This will aid in leading a fulfilling and independent life.

### Behavior Therapy

Behavior disorders are frequent in these children and can create problems in their everyday life. Most common of these disorders are agitation, self-injurious behavior (self-hitting, head banging) sleep disturbances (night-waking, early waking), ADHD and aggression (kicking, hitting, biting, breaking windows, screaming). About 20–35% of them also have a comorbidity of psychiatric etiology. Behavior assessment scale for Indian children (BASIC-MR) can be used to quantify the behavioral problems before giving the intervention. Self-injurious behavior, temper tantrums and aggression can be handled by using behavioral approach. Pharmacological treatment is effective for ADHD.

### Family Counseling

Empowering parents through parent education helps them to understand the needs of their child; assist the child in the learning process; handle the associated problems; and do advocacy for their children.

Significant aspect in the management of a child with intellectual disabilities is parental support. No doubt that ID is considered a static disorder, but the needs of the child and the family are bound to change from time to time. As the child grows older, the goals need to be reassessed and more information may be necessary to be given to the parents. As the case may be, the intervention plans may also need to be modified. Encouraging the parents to come in to the hospital/clinic for future clarifications and support is also very crucial. Providing them with supports in the society is also important.

### Nutritional Counseling

In galactosemia, treatment with a galactose-free diet prevents life-threatening liver failure, but despite good diet control, a majority of children may develop speech delay, low IQ scores and ataxia.

### Medical Intervention

No specific pharmacologic treatment is available for the cognitive impairment in the child. Medications, if prescribed, need to be targeted toward associated problems or comorbid associations. For example, a child with Down's syndrome may be vulnerable to infections and may also need supportive therapy or treatment for, hearing and vision problems, digestive problems, cardiac problems, lung defects, epileptic seizures and thyroid problems.

Inform the parents about the associated conditions that the child may have. Therapies such as speech therapy, occupational therapy or physiotherapy may be recommended as per the individual needs of the child. In some cases, prescription of anticonvulsant medications for seizures may be needed. Involving a speech therapist, a physiotherapist or an occupational therapist may be necessary.

### Leisure and Recreational Needs

In addition to the educational needs, it is very imperative to address the social and recreational needs of the child with intellectual disabilities. The goals of the leisure and recreational program are to support these persons to participate in meaningful recreation, leisure and volunteer activities of their choice. Encourage them to indulge in play activities (physical coordination, weight management and cardiovascular fitness).

### PROGNOSIS

The prognosis for children with intellectual disabilities depends on the underlying cause, the degree of the ID and the presence of the associated medical conditions. Children with intellectual disabilities reach their milestones as per the degree of the disability that the child has.

Individuals *requiring intermittent supports* reach the usual milestones, but they do it at their own pace. With supportive special education, speech therapy, medical care along with love and support from the family, they can be helped to develop functional literacy (until 5th or 6th std. level). They can be helped to reach their potential, gain economic and social independence with periodic supervision. Life expectancy is not adversely affected. Children with Down's syndrome generally live actively up to 50 years and beyond.

For intellectually disabled individuals *requiring limited supports*, the goal of education is to enhance the adaptive skills and vocational skills. Academically, they can reach up to second std. level. They may be trained to do specific job and will be able to work in sheltered workshops.

For individuals with ID *requiring extensive or pervasive support*, they function at preschool level, and will need extensive, continuous support through their lives. Having associated conditions like cerebral palsy or sensory impairments will also impact their adaptive functioning. They continue to live with their parents/siblings, as they need lot of support for their everyday living and for their severe medical problem.

In the West, the median life expectancies are 74 years, 67 years, and 58 years for people with mild, moderate and severe levels of intellectual disabilities. No such data is available for the Indian population.

### PREVENTION

#### Primary Prevention

It seeks to prevent the onset or occurrence of the problem. Advances in medical technology can aid in prevention as follows:

##### Immunization

Vaccination of girls with rubella vaccine should be encouraged to prevent fetal rubella occurring in the first trimester of pregnancy. Rh immune globulin (RhoGAM) usage for Rh positive pregnant women can prevent intellectual disabilities. Usage of Hib vaccine for preventing Hib meningitis can also prevent innumerable cases of intellectual disabilities in children.

#### Genetic Counseling

Family history indicates intellectual disabilities among family members. Consanguineous marriages have high chances of manifesting metabolic disorders with recessive inheritance. Late motherhood has high chances of a child being born with Down's syndrome. Genetic testing by amniocentesis and chorion villus sampling (CVS) could reduce the incidence of intellectual disabilities.

#### Obstetric Supervision

During labor, good obstetric supervision is essential to prevent occurrence of birth asphyxia, injuries, jaundice and sepsis.

#### Screening and Surveillance

Under the RBSK, which is a new initiative of the Ministry of Health and Family Welfare, 2013, it is mandatory to screen for *Down's syndrome* for all children between birth and 18 in the rural and urban slum groups. Regular pediatric surveillance is needed for the child at risk.

#### Awareness Training Programs

Educate young mothers about the harmful impact of intake of alcohol as fetal alcohol spectrum disorder is the most common known preventable cause of ID. Toxic exposure through environmental pollutants (e.g., lead poisoning) and through maternal substance abuse are avertable causes that can be fought with education and training. During pregnancy, good antenatal care, avoidance of teratogenic drugs, hormones, iodides and antithyroid drugs is needed. Healthy diet with folic acid in the diet reduces the chance of ID in the fetus. Prevent use of lead-based painted toys. Awareness on early detection in rural and urban areas will be of assistance in the *at risk* children to get the right support and intervention at the accurate time.

#### Secondary Prevention

Secondary prevention efforts should be directed to children who are born with a condition that might otherwise result in intellectual disabilities.

- Intellectual disability due to PKU can be easily prevented by a simple blood test followed up by phenylalanine-restricted diet. Most children with PKU who receive treatment have normal intellectual development. The incidence of PKU is highest in Turkey (1 in 2,600 births), whereas it is 1 in 18,300 births in India. Since the incidence of PKU is low in India, neonatal screening is not cost-effective or recommended.
- Incidence of CH is quite high (1 in 1,000 to 1 in 4,000). Cases of CH can be prevented by newborn screening and use of thyroid hormone replacement therapy. Indian babies ideally should be screened for CH. Newborn screening is making its progress in India. Kerala has started screening for 5 disorders from February 2013, and Gujarat is beginning to follow this trend.
- Use of surgery for implants for hydrocephalus.
- Empowering the child and the families with ID will help in stress reduction among the caregivers.

#### Tertiary Prevention

Measures are taken to reduce or limit impairments and disabilities, and to promote the patients' adjustment to *irremediable conditions*. Tertiary prevention seeks to limit the adverse effect of an existing problem while maximising the child's potential. Early intervention is the kind of tertiary intervention that has to be promoted for children with intellectual disabilities.

### IN A NUTSHELL

1. Intellectual disability is defined as consistently subaverage intellectual functioning accompanied by impairments in both cognitive functioning and adaptive skills with the onset before 18 years.
2. Early screening helps to anticipate associated comorbidities and help families to seek early intervention, which will ensure development of full potential of these children.
3. Recommend hearing tests as language delays can also be due to other developmental disabilities like hearing impairment, autism.
4. Abnormal dysmorphic features may or may not be significant predictors.
5. Magnetic resonance imaging and EEG yield specific diagnosis only in 7–8%. Patient management is not enhanced with MRI and CT scans of Down's syndrome, fragile X syndrome and hence need not be recommended in all cases of ID. Utility of CT or MRI scan is unclear when no neurological signs are present or when head circumference is normal. Chromosomal arrays are the highest yielding tools for ID of unknown etiology and are preferred over karyotyping and FISH assays.
6. Good history-taking and thorough physical examination can lead to diagnosis in most cases with intellectual disability.
7. Counsel the parents together with sensitivity, empathy and present information, in simple helpful language to the parents, emphasizing the prognosis.
8. Interventions which range from medical therapies to education to support groups will improve the quality of life of the child/family.

## Chapter 20.6

# Visual Impairment

Nikhil Rishikeshi, Sucheta Kulkarni

Visual impairment is defined as a functional limitation of the eye(s) or visual system and can manifest as reduced visual acuity or contrast sensitivity, visual field loss, photophobia, diplopia, visual distortion, visual perceptual difficulties, or any combination of the above. These functional limitations can result from congenital (e.g., prenatal or postnatal trauma, genetic or developmental abnormalities), hereditary (e.g., retinitis pigmentosa or Stargardt macular degeneration), or acquired conditions (e.g., ocular infection or disease, trauma, age-related changes, or systemic disease).

An impairment of the visual system present at birth, or developing shortly thereafter, can adversely affect development. Visually impaired children are often developmentally delayed in the areas of gross and fine motor skills and perception. For students, the inability to read standard-sized print, to see the chalkboard, overhead projection, or the computer, or to discriminate color can have a significant impact on their educational development. A visual impairment can cause disability by significantly interfering with one's ability to function independently, to perform activities of daily living, and/or to travel safely through the environment.

Specific problems include, but are not limited to, loss of the ability to read, inability or limitation with respect to driving, difficulty performing work-related tasks or leisure activities, and/or inability to recognize faces of familiar people. When these disabilities limit personal or socioeconomic independence, a visual handicap exists.

The primary justification for early identification of visual impairment in infants relates to its impact on the psychomotor development, cognitive achievements and social/emotional development. Delayed identification and management of visual impairment may impede the child's ability to adapt to family and community life and may mimic or cause behavioral problems.

## DEFINITION

The term *visual impairment* refers to a functional limitation of the eye(s) or visual system due to a disorder or disease that can result in a visual disability or a visual handicap. For example, retinitis pigmentosa (a disorder) can result in reduced visual acuity (an impairment in vision). A visual disability is a limitation of the ability (ies) of the individual (in this example, the inability to read small print or night blindness), and a visual handicap refers to a limitation of personal and socioeconomic independence. Simply put, a visual impairment may be considered as vision inadequate for an individual's needs.

## Severity of Visual Impairment

The World Health Organization (WHO) classifies levels of visual impairment based on visual acuity and/or visual field limitation, and defines blindness as profound impairment (this can refer to blindness of one eye or blindness of the individual). The WHO definition of blindness specifies visual acuity less than 20/400 and/or remaining visual field less than 10 degrees in the better seeing eye. Visual acuity of 20/70–20/400 (inclusive) is considered moderate visual impairment or low vision (**Table 1**). The National Eye Institute defines low vision more loosely, as a visual impairment not correctable by standard glasses, contact lenses, medication or

**Table 1** Categories of visual disability (classification currently in use)

Category	Better eye*	Worse eye*	Percentage impairment
Category 0	20/30–20/60	20/80–20/120	20
Category I	20/60–20/120	20/200 to nil	40
Category II	20/130–20/300 or field of vision 100–200	20/400 to nil	75
Category III	20/400–20/1,200 or field of vision 100	20/8,000 to nil	100
Category IV	20/8,000 to nil or field of vision 100	20/8000 to nil	100
One-eyed persons	20/20 20/8,000 to nil or field of vision 10–30 degrees		

\*With correcting lenses

surgery, that interfere with the ability to perform activities of daily living.

The existing classifications do not consider loss of function due to hemianopia, loss of contrast sensitivity, photophobia, visual distortion, diplopia, or visual perceptual difficulties. A classification system that considers the functional loss of the patient, rather than simply visual acuity or field loss, has been recommended.

The International Classification of Diseases-10 (ICD-10) International Classification of Impairments, Disabilities and Handicaps (ICIDH) has been developed to take into account these and other relevant factors. According to ICD-10, there are four levels of visual function: normal vision; moderate visual impairment; severe visual impairment; and blindness. Moderate visual impairment combined with severe visual impairment is grouped under the term *low vision*: low vision taken together with blindness represents all visual impairment. Many visually impaired individuals do not meet the current criteria for legal blindness and thus are not entitled to benefits and services that would seem appropriate. This notwithstanding, visual acuity, visual field, and contrast sensitivity are the most clinically useful quantifiers of visual impairment. Often, more than one function is affected.

## PREVALENCE

An estimated 19 million children are visually impaired worldwide. Of these, 12 million children are visually impaired due to refractive errors, a condition that could be easily diagnosed and corrected. 1.4 million are irreversibly blind for the rest of their lives. Approximately, 1.4 million children aged 0–14 years are blind, defined as a corrected visual acuity in the better eye of less than 3/60 (Thylefors, Négrel, Pararajasegaram, and Dadzie; World Health Organization, 2009). It is important to know that 80% of all visual impairment can be cured.

## ETIOLOGY

Worldwide, vitamin A deficiency is still a very important cause of childhood blindness. Predominant causes of blindness among children in the poorest countries of the world include: corneal scarring due to vitamin A deficiency, measles infection, ophthalmia neonatorum, and the effects of harmful traditional eye remedies. More than 12 million children age 5–15 are visually impaired due to uncorrected refractive errors as a result of near-sightedness, far-sightedness, or astigmatism (WHO, 2009). Refractive errors if not corrected at the right time can lead to amblyopia.

## Amblyopia

It refers to partial or complete loss of vision in one eye caused by conditions that affect the normal development of vision without any structural or organic ocular defect. It has a devastating effect on development of binocular single vision and stereopsis. In amblyopia, the brain favors one eye over the other. The other eye is ignored. It is not adequately stimulated and the visual brain cells do not mature normally. Amblyopia is the most common cause of monocular blindness, partial or complete blindness in one eye. Amblyopia affects 2-3% of children in the world.

Causes include strabismus, ptosis of one eyelid, stimulus deprivation amblyopia, disease of the cornea, congenital cataract, and injury to the eye of a young child. Any pathology that affects the normal development of the visual system causes irreversible visual loss, i.e., amblyopia if not treated very early and very aggressively.

All it takes for prevention of this potentially severe visual impairment is early detection and management by treatment of the causes—spectacles or contact lenses/occlusion or patching therapy/surgery.

## Cortical Visual Impairment

It is a form of visual impairment caused by a brain problem rather than an eye problem [the latter is sometimes termed *ocular visual impairment* when discussed in contrast to cortical visual impairment (CVI)]. Some people have both CVI and a form of ocular visual impairment.

Cortical visual impairment is also sometimes known as cortical blindness, although most people with CVI are not totally blind. The term neurological visual impairment (NVI) covers both CVI and total cortical blindness. Delayed visual maturation, another form of NVI, is similar to CVI, except the child's visual difficulties resolve in a few months. Though the vision of a person with CVI may change, it rarely if ever becomes totally normal. The major causes of CVI are as follows: asphyxia, hypoxia, developmental brain defects; head injury; hydrocephalus and infections of the central nervous system, such as meningitis and encephalitis.

Various causes of visual handicaps are discussed in detail elsewhere in this book (see Section 48 on eye and its diseases).

## BRUCKNER TEST (RED REFLEX TESTING)

Red reflex testing is vital for early detection of vision and potentially life-threatening abnormalities such as cataracts, glaucoma, retinoblastoma, retinal abnormalities, systemic diseases with ocular manifestations, and high refractive errors.

The American Academy of Pediatrics currently recommends red reflex assessment as a component of the eye evaluation in the neonatal period and during all subsequent routine health supervision visits.

## MANAGEMENT

Management goals and strategies have to be realistically and meticulously crafted to suit every individual, depending on the following: degree of visual impairment, disability, or handicap; underlying cause of visual impairment and prognosis; patient's age and developmental level; overall health status of the patient; other physical impairments which may affect the ability to participate in vision rehabilitation; patient's adjustment to vision loss; patient's expectations and motivation; and patient's (cognitive) ability to participate in the rehabilitation process.

Early diagnosis and referral to tertiary eye care centers cannot be stressed enough. Rehabilitation of the child at all levels and stages of development is of paramount importance. Prescription of appropriate spectacles, occlusion therapy for amblyopia (lazy eye), medical or surgical management as indicated and low visual aids form the pillars of management of all of these conditions. Children with visual impairment who do not improve even after prescription of optimum spectacles or contact lenses/surgery wherever needed, or even after necessary amblyopia therapy, need to be encouraged to make full use of whatever residual visual acuity is present with the help of a phenomenal range of low visual aids, hand held magnifiers, stand magnifiers, monocular and binocular telescopes.

### IN A NUTSHELL

1. There is a wide plethora of conditions that cause visual impairment in children.
2. Most causes of childhood blindness are preventable if recognized and treated early.

Wright KW. *Pediatric Ophthalmology for Pediatricians*. Baltimore, MD: Williams and Wilkins; 1999.

## Chapter 20.7

# Hearing Impairment

Neelam Vaid

Hearing loss is the most common sensory deficit in humans today. As per World Health Organization (WHO) estimates in India, there are approximately 63 million people, who are suffering from significant auditory impairment; this places the estimated prevalence at 6.3% in Indian population. Four of every thousand children in India have severe to profound hearing loss. This is much more than other conditions for which neonates are routinely screened such as congenital hypothyroidism, phenylketonuria and other inborn errors of metabolism. As per National Sample Survey Organization (NSSO) survey, currently there are 291 persons per one lakh population who are suffering from severe to profound hearing loss. Of these, a large percentage is children between the ages of 0–14 years. It is indeed a big challenge to provide education and employment to this large population. There are only 540–550 special schools catering to 3% of children with hearing impairment, in India.

### DEVELOPMENT OF HEARING

The anatomical parts of the ears develop in the first 20 weeks of intrauterine gestation. The organ of Corti is differentiated to such a degree that by 20 weeks the fetus can hear and respond to fluid borne sounds. At about 25 weeks of gestation the auditory system is functional. The period from 25 weeks of gestation to 5–6 months of age is the most critical for the development of hearing as unlike

the visual system the auditory system requires external stimulation for development.

The most intensive period of hearing and speech and language development is the first 3 years of life when the brain neuroplasticity is optimum. By 6 months of age, most children recognize the basic sounds of their native language.

### Hearing and Speech and Language Milestones

Hearing is critical to development of speech and language and learning. It is imperative that pediatricians know about the normal milestones related to hearing and speech. These too should be addressed during routine visits by the child and the family. An outline is provided by the American Speech, Language and Hearing Association (**Table 1**). A detailed description is available at <http://www.asha.org/public/speech/development/chart.htm>.

### HEARING IMPAIRMENT

It is defined as the inability to perceive or identify sound due to auditory problems. It can be bilateral or unilateral. Depending on the magnitude of hearing loss it is classified as mild (26–40 dB), moderate (41–55 dB), moderately severe (56–70 dB), severe (71–90 dB) or profound hearing loss (+91 dB; **Fig. 1**). Hearing loss up to 10–15 dB is normal.

### Types of Hearing Impairment

Depending on which part of the auditory system is affected, hearing loss can be of three types:

#### Conductive Hearing Loss

This is due to a problem in the outer and/or the middle ear. The common causes are: (a) Otitis media—associated with temporary

**Table 1** Milestones of hearing, speech and language

Hearing	Speech and language
Birth–3 months <ul style="list-style-type: none"> <li>Startles to loud sounds</li> <li>Quiets or smiles when spoken to</li> <li>Seems to recognize your voice and quiets if crying</li> <li>Increases or decreases sucking behavior in response to sound</li> </ul>	Birth–3 months <ul style="list-style-type: none"> <li>Makes pleasure sounds (cooing, gurgling)</li> <li>Cries differently for different needs</li> <li>Smiles when sees you</li> </ul>
4–6 months <ul style="list-style-type: none"> <li>Moves eyes in the direction of sounds</li> <li>Responds to changes in tones of your voice</li> <li>Notifies toys that make sounds</li> <li>Pays attention to music</li> </ul>	4–6 months <ul style="list-style-type: none"> <li>Babbling sounds more speech-like with many different sounds, including p, b and m</li> <li>Vocalizes excitement and displeasure</li> <li>Makes gurgling sounds when left alone and when playing with you</li> </ul>
7 months to 1 year <ul style="list-style-type: none"> <li>Enjoys games like peek-a-boo and pat-a-cake</li> <li>Turns and looks in the direction of sounds</li> <li>Listens when spoken to</li> <li>Recognizes words for common items, like <i>cup</i>, <i>shoe</i>, <i>juice</i></li> <li>Begins to respond to requests (<i>Come here</i>, <i>Want more?</i>)</li> </ul>	7 months to 1 year <ul style="list-style-type: none"> <li>Babbling has both long and short groups of sounds, such as <i>tata</i>, <i>upup</i>, <i>bibibibi</i></li> <li>Uses speech and non-crying sounds to get and keep attention</li> <li>Imitates different speech sounds</li> <li>Has one or two words (bye-bye, dada, mama), although they may not be clear</li> </ul>
1–2 years <ul style="list-style-type: none"> <li>Points to a few body parts when asked</li> <li>Follows simple commands and understands simple questions (<i>Roll the ball</i>, <i>Kiss the baby</i>, <i>Where's your shoe?</i>)</li> <li>Listens to simple stories, songs and rhymes</li> <li>Points to pictures in a book when named</li> </ul>	1–2 years <ul style="list-style-type: none"> <li>Says more words every month</li> <li>Uses some 1–2 word questions (<i>Where kitty?</i>, <i>Go bye-bye</i>, <i>What's that?</i>)</li> <li>Puts 2 words together (<i>more cookie</i>, <i>no juice</i>, <i>mommy book</i>)</li> <li>Uses many different consonant sounds at the beginning of words</li> <li>Vocabulary of 200 plus words</li> </ul>
2–3 years <ul style="list-style-type: none"> <li>Understands differences in meaning (<i>go-stop</i>, <i>in-on</i>, <i>big-little</i>, <i>up-down</i>)</li> <li>Follows two requests (<i>Get the book and put it on the table</i>)</li> </ul>	2–3 years <ul style="list-style-type: none"> <li>Has a word for almost everything</li> <li>Uses 2–3 word <i>sentences</i> to talk about and ask for things</li> <li>Speech is understood by familiar listeners most of the time</li> </ul>

Source: American Speech, Language and Hearing Association (ASHA).

**Figure 1** Categorization of hearing loss

and fluctuating hearing loss. Medical therapy and/or surgical intervention can reverse this hearing loss; (b) Impacted wax/cerumen; and (c) Congenital aural atresia—this is a failure of development of the external and middle ear and is commonly associated with microtia (small ears) or absent pinna. This may have associated cardiac and renal anomalies.

### Sensorineural Hearing Loss

This is due to a problem in the inner ear, i.e., the cochlea or the auditory nerve and its central connections. This type of hearing loss is usually permanent and irreversible. 21% of congenital sensorineural loss is caused by inner ear dysplasia which is due to genetic abnormalities. These include rudimentary otocyst, cochlear aplasia/hypoplasia, cystic cochleovestibular anomaly, Mondini deformity, X-linked deafness, large vestibular aqueduct syndrome, and cochlear aperture anomalies.

### Mixed Hearing Loss

This is a combination of both conductive and sensorineural hearing loss.

## Etiology

### Congenital Hearing Impairment

*Genetic factors* contribute to more than 50% of congenital hearing loss and could be syndromic (30%) or nonsyndromic (70%). The word syndromic implies an association of hearing impairment with other clinical distinctive features. These can be inherited in an autosomal dominant, autosomal recessive, X-linked recessive or mitochondrial pattern. More than 300 syndromes are associated with hearing impairment.

*Intrauterine factors* (8%) such as toxoplasmosis, other (syphilis, varicella-zoster, parvovirus B19), rubella, cytomegalovirus and herpes (TORCH) infections, human immunodeficiency virus, maternal diabetes, toxemia of pregnancy and consumption of certain toxins by the mother, e.g., alcohol, cocaine or ototoxic drugs, e.g., streptomycin during pregnancy can cause hearing impairment.

*Perinatal causes* (12%) of hearing impairment are prematurity, low birthweight (< 1,500 g), birth hypoxia, severe hyperbilirubinemia and sepsis.

### Acquired Hearing Loss

Acquired hearing loss can be due to otitis media, meningitis, head trauma, autoimmune factors, encephalitis, and other. In children, otitis media and bacterial meningitis are the most common cause of postnatal deafness. In *H. influenzae* meningitis, 40% of survivors will have some degree of hearing impairment. 4% of these will develop profound hearing loss. Associated seizures, cranial nerve neuropathy, prolonged hospitalization, delay in treatment for more than 48 hours and low sugar in cerebrospinal fluid are predictors for the development of hearing loss in patients with meningitis. Patients with *S. Pneumoniae* meningitis are predisposed to develop obstruction of the cochlea (labyrinthitis ossificans). This can begin as early as 2 weeks after the attack of meningitis. It increases with time and is usually bilateral.

No etiology is found in 20–30% children and these are labeled as *idiopathic*. Conditions with a high risk of associated hearing impairment are listed in **Box 1**.

### Effects of Hearing Impairment on Development

Hearing impairment affects speech and development in following ways:

- There is a delay in the development of receptive and expressive communication skills.
- This leads to delayed speech and language development which has a detrimental effect on the academic performance of the child.
- The children become socially isolated and frustrated. They have a poor self-esteem.
- This results in limited vocational options for these individuals as most professions need competent communication skills today.

Some of the psychological problems associated with hearing impairment are behavioral issues, low self-esteem, depression and introversion. Behavioral problems like aggression or hyperactivity are due to internal issues like depression, anxiety and inability to communicate. These children are usually described as shy/introverts. This is because communicating takes a lot of effort on their part. Children with sensorineural hearing loss have higher rates of behavioral issues (30–38%) than normal hearing children (3–18%).

Permanent childhood hearing loss, therefore, has major developmental impacts on children's literacy, psychosocial functioning and academic achievement (JCIH 2000). Children with hearing loss who begin intervention earlier have significantly better developmental outcomes than similar children who begin intervention later. Research shows that children diagnosed with hearing loss receiving intervention before 6 months of age achieve hearing and speech skills comparable to their normal peers.

## NEONATAL HEARING SCREENING

*Hearing loss is a neurological emergency as the child has already lost 20 weeks of intrauterine auditory stimulation. Learning to listen is time-bound as the child has a limited window to catch up with the normal hearing peers, i.e., 0–3.5 years.*

Early detection of hearing loss is essential to ensure that hearing impaired children get equal opportunities as their normal hearing peers. Without such programs, the average age of diagnosis of hearing impairment is 24 months, resulting in significant delays in speech language, social, cognitive and emotional development. Mild and moderate hearing loss is often undetected until school age. Nagapoornima et al. have reported a high incidence of hearing impairment, 5.60/1,000 in a standardized neonatal population at risk and not at risk. This warrants urgent implementation of neonatal hearing screening in India.

**BOX 1 Conditions with high-risk of hearing impairment**

1. Caregiver concern regarding hearing, speech, language or developmental delay
2. Family history of permanent childhood hearing loss
3. Neonatal intensive care of more than 5 days or any of the following regardless of length of stay: extracorporeal membrane oxygenation, assisted ventilation, exposure to ototoxic medications (gentamycin and tobramycin) or loop diuretics (furosemide/lasix), and hyperbilirubinemia that requires exchange transfusion
4. In utero infections, such as cytomegalovirus, herpes, rubella, syphilis and toxoplasmosis
5. Craniofacial anomalies, including those that involve the pinna, ear canal, ear tags, ear pits and temporal bone anomalies
6. Physical findings, such as white forelock, that are associated with a syndrome known to include a sensorineural or permanent conductive hearing loss
7. Syndromes associated with hearing loss or progressive or late-onset hearing loss, such as neurofibromatosis, osteopetrosis, and Usher syndrome; other frequently identified syndromes include Waardenburg, Alport, Pendred, and Jervell and Lange-Nielsen
8. Neurodegenerative disorders, such as Hunter syndrome, or sensory motor neuropathies, such as Friedreich ataxia and Charcot-Marie-Tooth syndrome
9. Culture-positive postnatal infections associated with sensorineural hearing loss, including confirmed bacterial and viral (especially herpes viruses and varicella) meningitis
10. Head trauma, especially basal skull/temporal bone fracture that requires hospitalization
11. Chemotherapy.

Overall known risk factors are present in only 50% of infants born with hearing loss. Also mild and moderate hearing loss is often undetected until school age. Therefore, universal neonatal hearing screening (UNHS) has replaced selective or high-risk screening. Most UNHS programs aim for screening by 1 month, confirmation of diagnosis by 3 months and intervention by 6 months. The American Academy of Pediatrics, Joint Committee on Infant Hearing (2007) recommends the 1–3–6 timeline. Hearing screening should be completed by 1 month of age. Those who fail the initial screening should undergo detailed audiologic evaluation by 3 months of age and intervention done not later than 6 months of age. The recommended protocol for healthy babies is shown in **Flow chart 1**. An important point is that to be considered as pass, both the ears must pass screening. High-risk babies and neonatal intensive care unit graduates have a high incidence of auditory neuropathy and delayed onset or progressive hearing loss which needs to be constantly monitored.

Screening can be done by *otoacoustic emission* (OAE) and/or automated auditory brainstem response (AABR) testing. OAE are generated by the outer hair cells of the cochlea in response to auditory input. AABR evaluates the auditory pathway from the external auditory canal to the brainstem. There have been numerous studies comparing OAE only, AABR only and two steps testing using OAE initially followed by AABR. The referral rate is lesser with the two-step protocol using OAE and AABR than a single step OAE program—1.8–5.8%. Using AABR alone had the lowest referral rate, i.e., less than 2%, however, had the highest cost per screening. Regardless of the screening results, all children should be constantly monitored for the development of age appropriate

auditory and communication skills. Any delay in these skills needs detailed evaluation by an audiologist.

## WORKUP OF A CHILD WITH HEARING IMPAIRMENT

The management of a child with hearing impairment involves a team comprising of an otorhinolaryngologist, pediatrician, audiologist, radiologist, clinical geneticist, child psychologist and speech and language pathologist. The recommended steps are outlined:

1. Detailed history taking with special focus on the high-risk factors, antenatal and perinatal details, consanguinity, history of hearing impairment in any other family members and history of any serious illness requiring hospitalization and administration of intravenous drugs.
2. Examination of the child to look for any syndromic features associated visual/motor/neurological development issues.
3. Examination of the ear, i.e., *otoscopy*. It is imperative to rule out the presence of wax or any acute/chronic infection in the ear which needs to be addressed before further management. Any associated anomalies in the ear, nose and throat region like aural atresia, cleft lip and/or palate, facial skeletal deformities and adenoid enlargement need to be ruled out.
4. Diagnostic audiology should be provided by an audiologist with experience in the evaluation of neonates and young children. The aim is to provide the following information: (a) Confirm the presence/absence of hearing impairment; (b) Assess the degree of hearing loss; (c) Determine which part of the auditory system is affected; and (d) Determine which frequencies are affected.

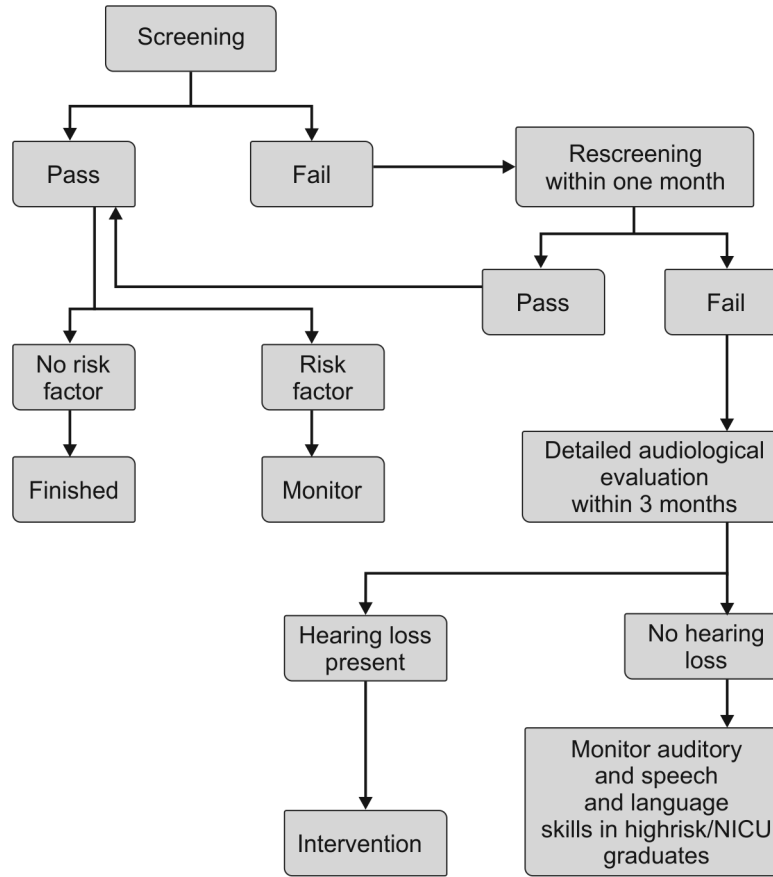

The Clinical Practice Guidelines recommended by the American Academy of Audiology for the assessment of auditory function in children has mentioned the following evaluations: (a) behavioral observation; (b) visual reinforcement audiometry; (c) conditioned play audiometry—frequency specific stimuli and speech audiometry; (d) physiologic assessment—impedance audiometry and OAE; and (e) electrophysiologic audiometry—auditory brainstem response (ABR) and auditory steady state response (ASSR). This is known as the *test battery* approach, i.e., all the above-mentioned tests are incorporated to confirm results. The gold standard of hearing measurement is behavioral assessment. The appropriate behavioral procedures depend upon the child's development, cognitive level and motor and visual development.

5. Anatomy of the ear is evaluated using dual modality radiological assessment comprising of both low dose high resolution computed tomography/cone beam computed tomography and magnetic resonance imaging.
6. Evaluation of the developmental age of the child by a developmental pediatrician and a child psychologist to rule out global developmental delays and look for other associated problems, like autism, learning disabilities and behavioral issues.
7. Complete assessment by a speech and language pathologist about the communicative skills of the child.

## TREATMENT

Intervention depends on the etiology of hearing impairment. Conductive hearing loss caused by disorders in the external and/or middle ear respond to medical and/or surgical line of management. Children with sensorineural hearing loss and congenital aural atresia need different auditory prosthesis, such as hearing aids/cochlear implants/bone anchored hearing aids (BAHA)/middle ear

**Flow chart 1** Neonatal screening for detection of hearing loss

Abbreviation: NICU, neonatal intensive care unit.

implants with therapy focused on developing their listening and speech and communicating skills. The choice of auditory prosthesis is dependent on the degree of hearing loss and the etiology.

### Hearing Aids

Children with mild to moderate hearing loss benefit from appropriately fitted hearing aids. A hearing aid is an electroacoustic device that amplifies sound. It is recommended to fit hearing aids in both the ears of children with hearing impairment to give them the benefit of binaural hearing.

### Cochlear Implants

These are a proven option for children with bilateral severe to profound hearing loss. A cochlear implant consists of an internal part which is surgically inserted and an external part which looks like a hearing aid. The technology converts acoustic signals to electrical signals and directly stimulates the surviving spiral ganglion cells in the cochlea. US Food and Drug Administration (FDA) permits implantation in children over the age of 12 months. Cochlear implantation is contraindicated in the presence of active middle ear disease and absent cochlear development. Till recently absence of the cochlear nerve was an absolute contraindication, however, certain studies are showing limited benefits with the cochlear implants in this subgroup of patients.

### Bone Conduction Hearing Aid

These are indicated for children with conductive or mixed loss due to abnormalities in the external or middle ear not amenable to ear surgery, e.g., severe congenital aural atresia or children in whom hearing aids are not feasible, e.g., chronically discharging ears. These are also an option in children with single-sided deafness. These can be done in children more than 5 years of age. Younger children are given a soft band which functions like a BAHA till they can undergo surgery.

### Active Middle Ear Implants

These are indicated for children with mixed/conductive hearing loss. These require great caution on the part of the surgeon due to the risk to the facial nerve in cases with aural atresia. Presently being done in Europe only, as this surgery in the US on children is still not approved by US FDA.

### Auditory Brain Stem Implants

It is a device which provides some level of hearing in people without a functioning cochlear nerve. These are indicated in children with absent cochlear nerves and severe labyrinthitis ossificans where cochlear implantation is not possible. As on now these are being implanted in children only in Europe.

## IN A NUTSHELL

1. Hearing loss is the most common sensory deficit in children.
2. Early detection and intervention ensure development of near normal speech and language for children with hearing impairment.
3. Diagnostic audiology should be provided by an audiologist with experience in the evaluation of neonates and young children. The aims are to: (a) confirm the presence/absence of hearing impairment; (b) assess the degree of hearing loss; (c) determine which part of the auditory system is affected; and (d) determine which frequencies are affected.
4. Behavioral observation, visual reinforcement audiometry, conditioned play audiometry, physiologic assessment—impedance audiometry and OAE, and electrophysiologic audiometry—ABR and ASSR constitute the *test battery* approach for diagnosis of hearing impairment.
5. Universal neonatal hearing screening needs to be implemented in India.

## Chapter 20.8

# Cerebral Palsy

Sharmila Banerjee Mukherjee

Cerebral palsy (CP) is the most common cause of chronic motor disability in childhood. In 2007, an international committee described CP as *a group of permanent disorders of movement and posture, causing limitation of activity, attributable to nonprogressive disturbances that occurred in the developing fetal or infant brain, often accompanied by disturbances of sensation, perception, cognition, communication and behavior, epilepsy and secondary musculoskeletal problems*. The Surveillance of Cerebral Palsy in Europe (SCPE) group recognizes five key elements defining CP: (1) an umbrella term, (2) permanent but not unchanging, (3) disorder of movement and/or posture and of motor function, (4) due to a nonprogressive interference, lesion or abnormality and (5) affecting the immature brain.

Cerebral palsy is a clinical phenotype of various types and degrees of motor impairment due to heterogeneous causes, resulting in a permanent single-time insult to the developing brain. Though the insult itself is nonprogressive, manifestations change due to natural progression, influence of intervention and/or development of complications.

### EPIDEMIOLOGY

In developed countries, systematic and valid epidemiological information is easily available. The Centers for Disease Control and Prevention (CDC) reports CP in 3.6/1,000 with a boy/girl ratio of 1.4:1. A prevalence of 2–3 cases of CP/1,000 livebirths has been reported from other countries. Over the years, studies have either shown a static trend or a minor increase probably reflecting increased survival of very premature babies. Community-based statistics are not available from developing countries including India.

### ETIOLOGY

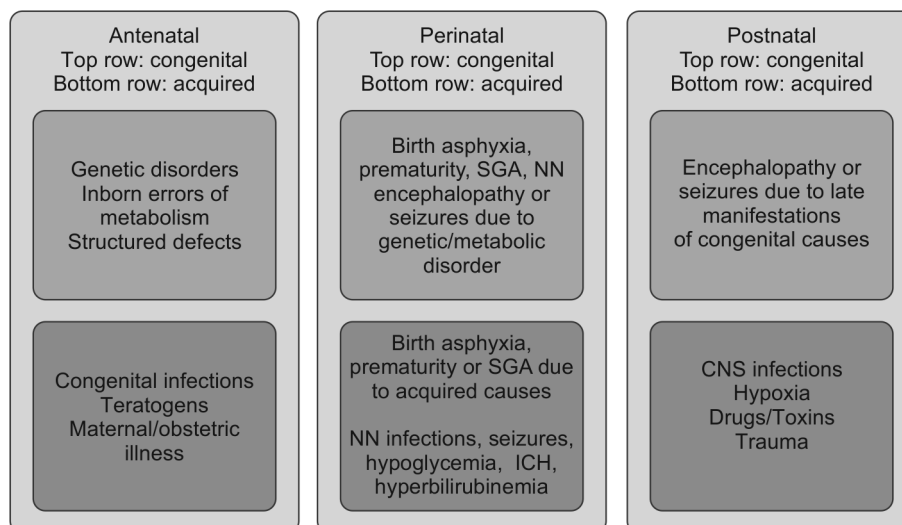

The primary insult to the developing brain is categorized as congenital, acquired or combined. This can be hypoxic, ischemic,

infectious or inflammatory, irrespective of cause. Timing of this insult can be antenatal, perinatal or postnatal. Although apparently synonymous, the difference is appreciable in **Figure 1**.

Earlier hypoxic injury at birth was thought to be the commonest cause of CP. Now it has been conclusively proven that it is responsible for less than 10% of cases. In 2003, the International Cerebral Palsy Task force criteria update added four essential criteria for defining an intrapartum event sufficient enough to cause CP: (1) metabolic acidosis with pH less than 7.2 and base deficit of greater than or equal to 12 mmol/L in fetal umbilical cord arterial sample at delivery; (2) early onset of moderate or severe neonatal encephalopathy in babies greater than or equal to 34 weeks' gestation; (3) spastic quadriplegia or dyskinetic CP; and (4) exclusion of identifiable causes (trauma, coagulation disorders, infectious conditions or genetic disorders). The SCPE states that in the absence of obvious insult at birth or later the underlying etiology may be considered antenatal. Precise etiology cannot be identified in 20–30% cases.

Certain factors have been found to have significantly higher associations with CP which may be causative. These can be preconceptional (fertility treatment), antenatal (neonatal stroke due to factor V Leiden, multiple pregnancies, maternal pre-eclampsia), natal (maternal hypotension, premature separation of membranes, low placental weight, low Apgar scores) and postnatal [requirement of admission in a neonatal intensive care unit (NICU), neonatal sepsis and respiratory disease].

In developed countries, most cases of CP are attributable to antenatal causes and preterm neonatal survivors. Associated factors are assisted conceptions and multiple pregnancies. In developing countries, although antenatal causes are maximal, the proportion of acquired causes is relatively more in contrast to developed countries. Indian data of a large cohort of children with CP over 10 years from the Postgraduate Institute of Medical Education and Research (PGIMER), Chandigarh revealed majority to be term deliveries, 59.8% due to congenital causes, 17.8% acquired and 22.4% combined. In the acquired group, 57.4% were due to central nervous system (CNS) infections, 30% bilirubin encephalopathy (mostly Rh incompatibility), 7.4% late hemorrhagic disease of the newborn or intracranial bleeds and 5.2% due to hypoglycemia/head injury. Compared with the results of an earlier study cases associated with prematurity, low birthweight, neonatal jaundice and birth asphyxia had increased significantly.

**Figure 1** Congenital and acquired causes of cerebral palsy according to timing of insult to the immature brain (antenatal, perinatal and postnatal)

## PATHOGENESIS

The basic pathophysiology is a cascade of harmful events that often begin in utero and continue during and after delivery. It depends upon underlying etiology, mechanisms of injury (hypoxic-ischemic or inflammatory), timing of insult, gestational age (< 34 weeks or older), neuroanatomical structure affected and genetic predisposition. A simplified version is depicted in **Flow chart 1**.

Any significant ischemic-hypoxemic insult triggers an excitotoxic cascade that causes secondary energy failure in the mitochondria. Hypoperfusion provokes protective redistribution of blood to the brain, heart and adrenals. When reperfusion occurs secondary to compensatory mechanisms, there is a massive influx of free oxygen radicals and calcium ions in the affected areas due to damaged ion channels. This ionic imbalance causes neuronal membrane depolarization and glutamate transporter failure in the presynaptic glia that normally removes glutamate from the synaptic cleft. When the increased synaptic glutamate spill over into the extracellular spaces, excitatory glutamate N-methyl-D-aspartate (NMDA) receptors get stimulated, which cause release of more free radicals and worsen the oxidative stress. Enzyme-mediated cellular damage and release of proapoptotic cytochrome C and apoptosis-inducing factors stimulate pathways leading to neuronal apoptosis. Lactic acid accumulation disrupts the mitochondrial respiratory chain. The cumulative effect is apoptosis and necrosis of brain cells with glia being more susceptible than neurons. The inflammatory cascade is triggered by maternal infection and makes the brain more sensitive to hypoxemic-ischemic injury.

The immature brain (< 34 weeks' gestation) is more prone to injury and oxidative stress. This is reflected in the characteristic magnetic resonance imaging (MRI) findings of *white matter damage of immaturity* (WMDI) seen in preterm babies with CP. The most common autopsy findings in the premature brain are subependymal, intraventricular or leptomeningeal hemorrhage.

In contrast, in term babies, brain structures rich in excitatory synapses like the deep basal ganglia, para-rolandic cortex and posterior putamen are more vulnerable to injury.

Genetic factors may contribute to susceptibility to inflammatory response. Male neurons in culture are more sensitive to death from exposure to NMDA and nitric oxide (NO) radicals and more vulnerable to autophagy than female neurons. This could be why CP is more common and more severe in boys. Functional polymorphism in the interleukin-6 gene has been associated with CP in term babies.

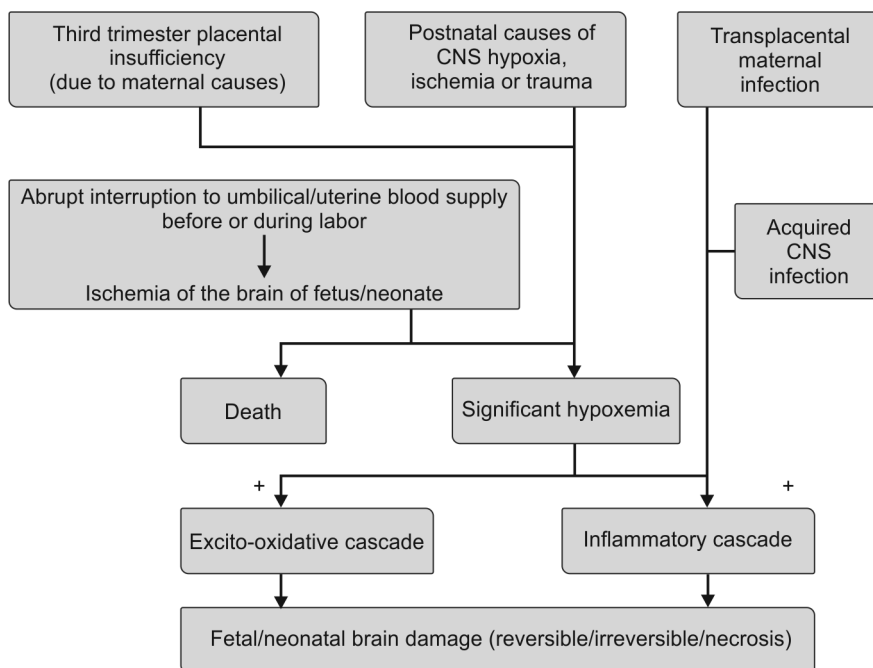

## CLASSIFICATION

This provides description of nature and severity and information regarding healthcare needs, thus enabling monitoring of change in individuals and comparison of data from different centers. The *topographic classification* is based on the distribution pattern of limb involvement, the *physiological classification* is based on the type of motor abnormality and the Swedish and SCPE classification systems combine both (**Table 1, Fig. 2, and Flow chart 2**).

In developed countries, spastic CP is seen in 85% (diplegia 35%, quadriplegia 20%, hemiplegia 25%) and extrapyramidal in 5%. Indian data reports 73% spastic (quadriplegic 51.5%, diplegic 34.5%, hemiplegic 13.8%), 7% dyskinetic/athetoid, 11.2% hypotonic/ataxic and 8.8% mixed.

In 2001, the International Classification of Functioning, Disability and Health (ICF) for developmental disabilities introduced the concept of defining impairment in body function and/or structures, limitation of activity, restriction in participation and environmental factors. **Flow chart 3** exemplifies ICF in a child with CP. The Gross Motor Function Classification Scale (GMFCS) (**Fig. 3**) and Manual Ability Classification scale (MACS) rate dysfunction in terms of overall mobility and upper limb function respectively (**Table 2**). The main drawback of these systems is that they cover only one aspect. A multiaxial classification essential for holistic understanding and appropriate management will be discussed later in this chapter.

**Flow chart 1** Pathogenesis of brain damage in cerebral palsy

**Table 1** Topographic, physiological and modified Swedish classification systems of cerebral palsy

Topographic classification	Physiological classification	Modified Swedish classification
Quadriplegia	Spastic	Spastic
Hemiplegia	Quadriplegia	Tetraplegic
Diplegia	Hemiplegia	Hemiplegic
Monoplegia	Diplegia	Diplegic
Triplegia	Extrapyramidal	Ataxic
	Mixed	Dyskinetic
		Choreoathetotic
		Dystonic

**Figure 2** Topographical classification of cerebral palsy

## CLINICAL MANIFESTATIONS

The diagnosis of CP is purely clinical.

### Presenting Complaints

One would assume that this would be primarily motor-related like delayed motor milestones, locomotor difficulties or abnormal movements. However, comorbid conditions commonly associated with CP may be equally or more incapacitating. The presenting complaints reported in the Indian study were developmental delay (88%), seizures (34.7%), problems of gait and posture (22.8%), speech delay (9.5%) and problematic behavior (5.9%).

### Motor Manifestations in Established Cerebral Palsy

It is easy to make a diagnosis by 18–24 months when decreased motor power is accompanied by the following easily recognizable signs:

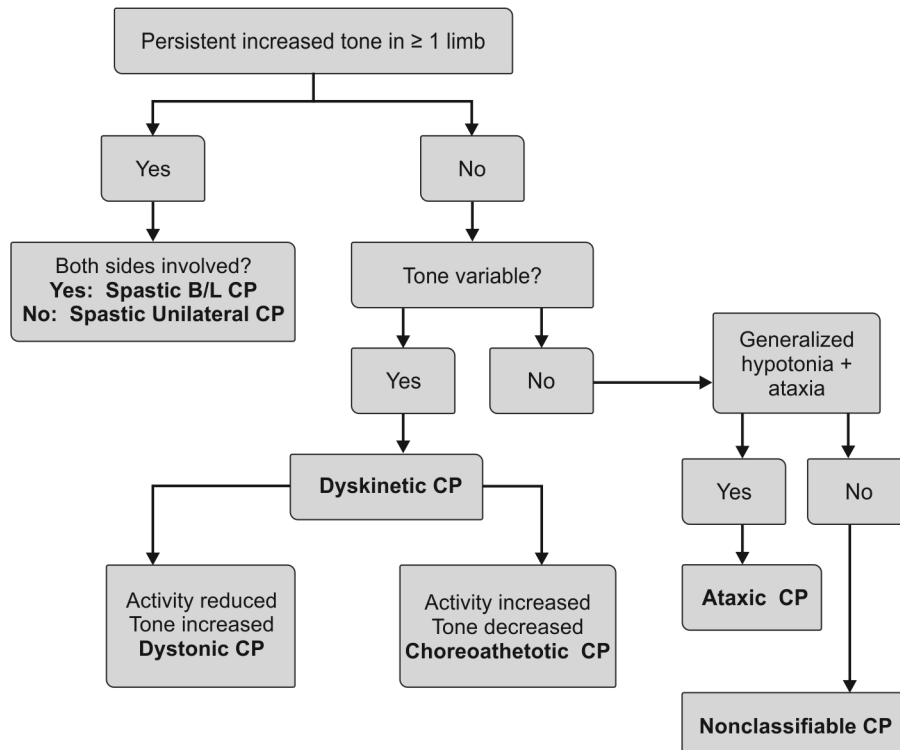

**Abnormal tone** Increased (spastic), decreased (ataxic) or variable (dyskinetic).

**Abnormal gait** Crouched (hip flexion, knee flexion and ankle dorsiflexion) and circumductive.

**Abnormal limb positioning** Characteristic upper limb postures are elbow flexion with pronation of forearm, flexion of the wrist and fingers and thumb in palm (**Figs 4A to C**). The lower limbs exhibit equinovag, equinovarus and pes valgus, flexion of the knees and hip subluxation (characterized by pelvic obliquity). Excessive adductor spasm causes scissoring.

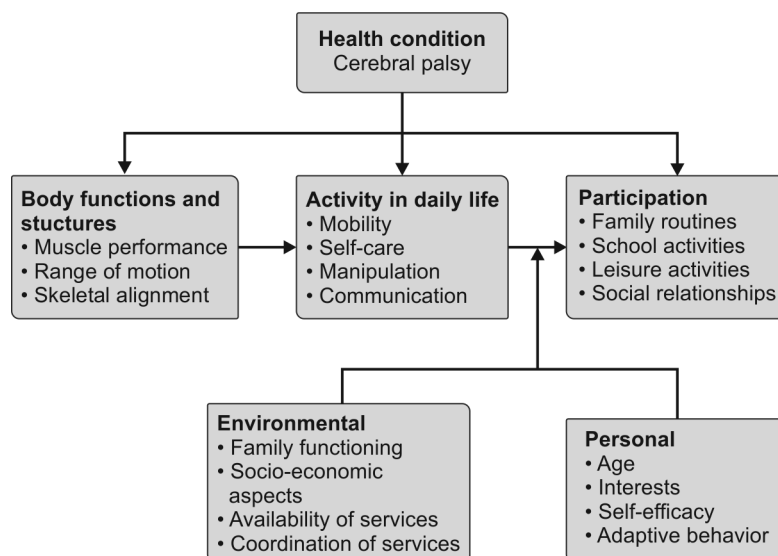

**Abnormal movements** Choreoathetosis, dystonia or both.

**Abnormal reflexes** Hyperreflexia of deep tendon reflexes, persistence of neonatal reflexes, persistent extensor plantar reflexes and failure of appearance of postural reflexes.

**Flow chart 2** Surveillance of Cerebral Palsy in Europe (SCPE) algorithm for classification of cerebral palsy

**Flow chart 3** The International Classification of Functioning, Disability and Health (ICF) framework applied to a child with cerebral palsy

Source: Reproduced with permission from WHO.

**Table 2** Manual Ability Classification System (MACS)

Level	Description of manual ability
I	Handles objects easily and successfully
II	Handles most objects but with somewhat reduced quality and/or speed of achievement
III	Handles objects with difficulty; needs help to prepare and/or modify activities
IV	Handles a limited selection of easily managed objects in adapted situations
V	Does not handle objects and has severely limited ability to perform even simple actions

Source: Reproduced with permission from Ann-Christin Eliasson and Peter Rosenbaum, Can Child Centre for Childhood Disability Research, Ontario.

Note that this is applicable for children with CP between 4 and 18 years. The cumulative manual ability of both hands is considered while staging.

### Manifestations in Evolving Cerebral Palsy

Recognition of this stage requires experience, keen observation and clinical acumen. Symptoms like delayed milestones, slightly more than normal tightness or limpness of the body or limbs appreciable while diapering or dressing the infant, difficulties in breastfeeding, repetitive tongue movements, impaired hearing or vision, squint or recurrent regurgitation may be indicative of evolving CP. One must keep a high degree of suspicion, especially in *at high-risk* babies (NICU graduates) and do a detailed developmental evaluation looking for any abnormal or asymmetrical patterns of movement or position while performing the developmental maneuvers (Table 3). Sometimes it is difficult to differentiate slight abnormalities from normal variation or transient tone abnormalities that can occur around 4–5 months of age. In these circumstances, parents should not be needlessly alarmed without justification. At the same time, it is extremely important for intervention to be started. Parents should be sensitively explained that the mild abnormalities detected may be a false alarm but nevertheless will require intervention and close follow-up for a few months.

### Changing Manifestations of Cerebral Palsy

This occurs due to natural progression of the primary injury, which although static in nature gets modified by the naturally ongoing maturation of the CNS (i.e., hypotonia evolving into spasticity due to the normal ongoing myelination) or age-dependent recognition of symptoms (speech delay or cognitive impairment becoming appreciable when child is older).

#### Nonmotor Manifestations

These are frequently seen in CP either due to the primary insult or secondary to other factors. Children with CP usually have multiple comorbid conditions that require documentation and monitoring for optimal management (Table 4). An individual's problem chart should record details of the following:

**Cognitive impairment** Global developmental delay/intellectual disability or learning disability manifests as delayed milestones and scholastic underachievement. This gets confounded by sensory impairments and motor restriction which lead to limited cognitive stimulation and experiential learning.

**Behavioral issues** These may be severe enough to interfere with daily functioning. They may be due to primary defects, drug side effects or faulty parenting practices.

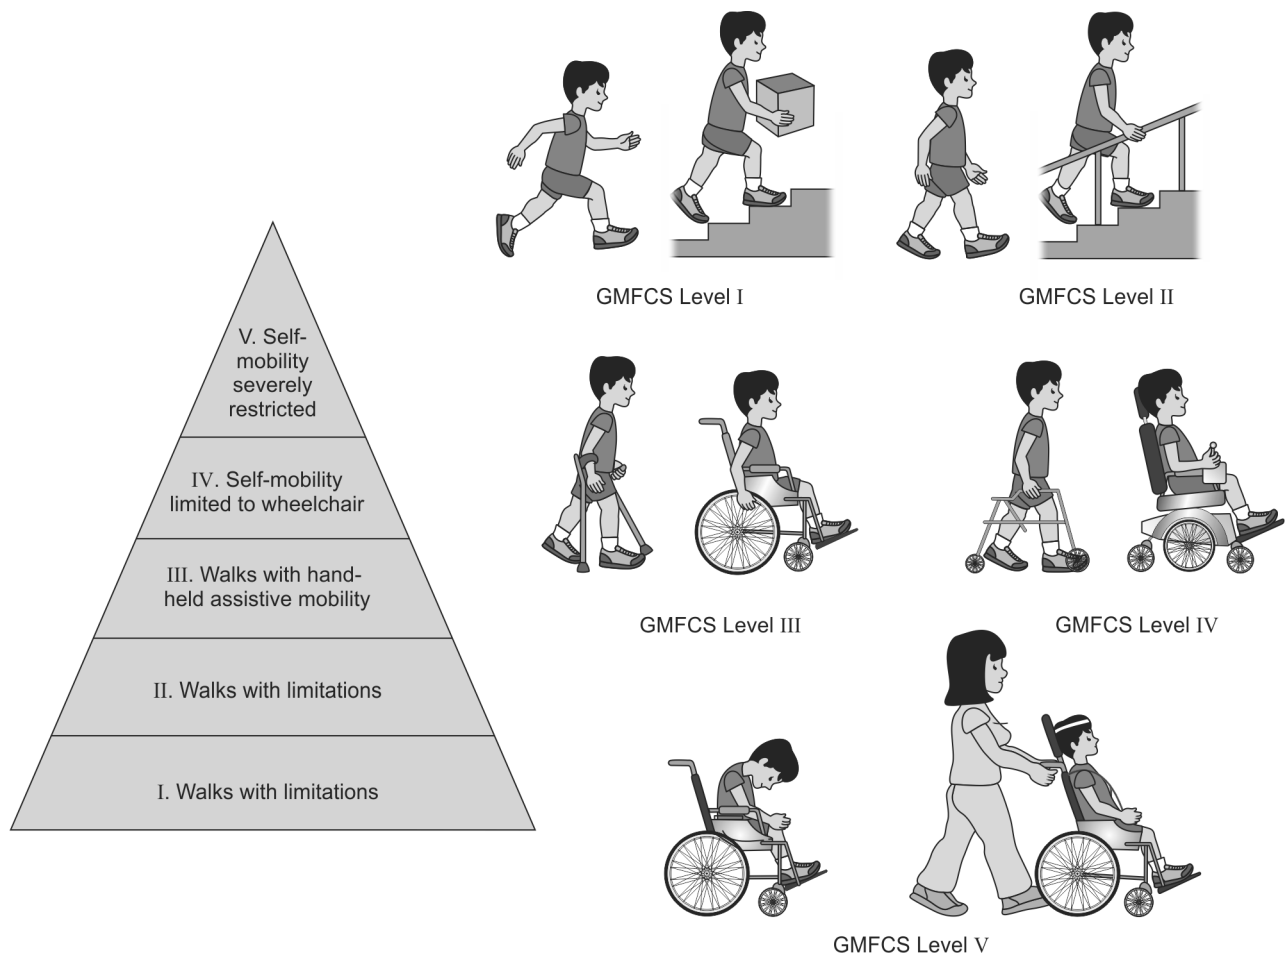

**Epilepsy** Nearly one-third have epilepsy with onset within the first 2 years. Generalized tonic-clonic seizures are most frequently seen. Seizure control often requires multiple anticonvulsants.

**Speech and language problems** These arise due to cognitive defects, hearing impairment or dysfunctional speech areas. Articulation defects are due to oromotor dysfunction and pseudobulbar palsy.

**Sensory impairment** These include cortical blindness, hearing impairment, perceptual deficits oromotor hypersensitivity and sensory disintegrative dysfunction.

**Ocular manifestation** These include strabismus, refractory errors, optic atrophy, nystagmus and visual impairment.

**Gastrointestinal problems** Poor dental hygiene, gastrointestinal motility disorders, gastroesophageal reflux (GER) and constipation are common.

**Figures 4A to C** Upper limb positions seen in cerebral palsy: (A) Flexion of wrist with slight splaying of fingers; (B) Pronation of forearm; (C) Flexion of fingers

Source: Dr Srishti Goel.

**Feeding problems** Difficulties in chewing and swallowing, choking, excessive drooling and food aversion can be due to causes like oromotor dysfunction, abnormal perioral sensory awareness, poor head stability, inability to self-feed and gastroesophageal reflux disease (GERD).

**Macronutrient and micronutrient deficiencies** This is attributable to decreased intake. Vitamin D deficiency is due to nonambulation, anticonvulsants, low sun exposure and poor calcium intake.

**Pain** This manifests as excessive crying or irritability. Causes are chronic muscle spasm, orthopedic complications, undetected dental problems, constipation and GERD.

### Orthopedic Complications

These include the following:

1. **Low impact fractures:** Due to associated severe osteopenia.
2. **Secondary abnormalities:** Spasticity results in disuse atrophy, joint contractures and limb length discrepancy. Deformities like femoral anteversion, external tibial torsion, talipes equinovagum and hip subluxation are referred to as *lever arm disease* due to a malaligned bony lever that impairs muscle function and affects gait. Hip subluxation occurs due to femoral neck valgus, persistent anteversion, soft tissue contractures and acetabular deformity. Lumbar scoliosis is seen in less than 10% of ambulatory children and 30–40% of nonambulatory children.

**Table 3** Signs indicative of early CP while performing developmental maneuvers

Developmental maneuvers	Significant findings
Supine	<ul style="list-style-type: none"> <li>• Head persistently in midline</li> <li>• Limbs unduly extended with persistent fisting of one or both hands</li> <li>• Reduced and/or asymmetrical spontaneous movements</li> <li>• Not tracking till 180° by 12 weeks</li> <li>• Not turning head to sound</li> </ul>
Prone	<ul style="list-style-type: none"> <li>• Head to side, not in midline by 12 weeks</li> <li>• Chin not raised off plane of surface by 6 weeks</li> <li>• Face not at 45–90° and no weight-bearing on forearms by 12 weeks</li> <li>• Pelvis still not flat by 12 weeks</li> <li>• Knees drawn under abdomen without extension of legs &gt; 6 weeks</li> </ul>
Pull to sit	<ul style="list-style-type: none"> <li>• Pronounced head lag</li> <li>• Spasm of hamstring felt in popliteal space and feeling of resistance with flexion of knees</li> <li>• Entire body rising spontaneously to feet</li> </ul>
Held sitting	<ul style="list-style-type: none"> <li>• Inability to lift chin up intermittently</li> <li>• Rounding of back pronounced</li> </ul>
Held standing	<ul style="list-style-type: none"> <li>• Unable to lift chin up momentarily beyond 8 weeks</li> <li>• Unable to bear weight at all</li> <li>• Abnormal degree of plantar flexion</li> </ul>
Ventral suspension	<ul style="list-style-type: none"> <li>• Excessive head lag with limbs hanging limply OR</li> <li>• Advanced head control—head above level of plane with increased extension of lower limbs</li> </ul>
Axillary suspension	<ul style="list-style-type: none"> <li>• Abnormal/asymmetrical extension of lower limbs</li> <li>• Abnormal adduction/scissoring of lower limbs</li> <li>• Feeling of sensation of slipping</li> </ul>

3. *Tertiary abnormalities:* These result from compensatory mechanisms adopted to overcome spasticity and secondary abnormalities in order to achieve ambulation, i.e., hamstring and recti femori involvement results in compensatory hip over-abduction and circumductive gait.

## Clinical Manifestations According to Cerebral Palsy Subtype

### Spastic Quadriplegic Cerebral Palsy

This is the most severe form with high association with intellectual disability, epilepsy, microcephaly, squint/visual impairment, pseudobulbar palsy, speech abnormalities and deformities (**Fig. 5**).

*Spastic diplegic cerebral palsy* This is most commonly seen in preterm babies (85%). Initial indicators are difficulties in diapering and *commando crawl* (self-propulsion by use of arms). Intellectual disability and epilepsy are less common but learning disability or sensory problems may be present.

*Hemiplegic cerebral palsy* Early indicators are persistent fisting, cortical thumb, hand preference in infancy and circumductive gait. As they grow older, asymmetry of posture and limb position become obvious (**Fig. 6**). Epilepsy and intellectual disability are relatively common.

*Dyskinetic cerebral palsy* Initially hypotonicity gradually evolves into dystonia, rigidity and abnormal postures. Intellectual disability and epilepsy are less common but commonly associated

speech difficulties, tongue thrust and drooling are often mistaken for severe cognitive impairment.

*Ataxic cerebral palsy* This is caused by cerebellar injury that affects the whole body. It is characterized by hypotonia, difficulty with balance and motor coordination and tremors.

*Mixed cerebral palsy* This is a combination of both spastic and extrapyramidal CP.

## CLINICAL EVALUATION

Preliminary evaluation comprises of a detailed history, general physical examination, extended neurological assessment, developmental assessment and evaluation of nature and severity of comorbidities and complications (**Table 5**). All children should be referred to other specialists.

## INVESTIGATIONS

### For Determining Etiology

Individualized, targeted and sequential investigations ensure a higher etiological yield.

*Neuroimaging* The pattern, extent and severity of lesions may determine etiology and timing of insult. MRI is preferable over computed tomography (CT) scan (except where cranial calcification is anticipated). **Table 6** illustrates the commonly known MRI-topographic-etiology correlates. Further investigations are planned accordingly. MRI findings in the European study were WMDI (42.5%), basal ganglia lesions (12.8%), cortical/subcortical lesions (9.4%), malformations (9.1%), focal infarcts (7.4%), miscellaneous (7.1%) and normal (11.7%). Indian literature reported hypoxic-ischemic changes (35.7%), periventricular leukomalacia (PVL) (13.4%), cerebral malformations (7.4%), nonspecific cerebral atrophy (12.8%), basal ganglia changes (5.8%) and others (11.5%). This corresponds to the difference in etiologies.

*Metabolic investigations* When the MRI is normal but there is clinical suspicion of a metabolic disorder according to history or examination (spastic diplegia or choreoathetoid CP without definite etiology), standard metabolic investigative protocol should be followed.

### Assessment of Comorbidities

*Cognitive impairment* Administration of specific validated psychometric diagnostic scales by a clinical psychologist.

*Behavioral issues* Determine parental responses to inappropriate behavior. If maladaptive behavior very severe, frequent, refer to clinical psychologist.

*Nutritional assessment* Assessment of dietary and water intake and investigations for micronutrient deficiencies including vitamin D levels annually.

*Others* Visual, hearing, speech and language assessment. Speech and language pathologist evaluation that should include a feeding assessment. Radiographs of affected joints, both hips at 18–24 months (subluxation may not be clinically apparent) and spine to exclude scoliosis. Orofacial evaluation is important.

## FINAL DIAGNOSIS

This should be multiaxial with the following components: physiological, topographic, ICF/functional and neuroradiological classification, etiology, timing of insult, comorbid conditions, complications and nutritional status. This helps in planning management, counseling, monitoring progress and prognostication. Certain conditions that mimic CP are given in **Table 7**. These can usually be excluded by a detailed evaluation.

**Table 4** Example of a problem chart of a child with cerebral palsy

Source: Dr Srishti Goel.

## MANAGEMENT

Intervention should start the moment CP is diagnosed or suspected. Without intervention the natural course is rapid deterioration of gait and motor function. Goals are enhancing acquisition of new skills, treating comorbid conditions and decreasing complications. Ideally it should be done by a multidisciplinary team (rehabilitative, medical and surgical) in a single center (**Fig. 7**). Any member can act as a team-leader whose responsibilities are mainly ensuring team coordination, scheduling group discussions on progress and appointments and updating the management chart (**Table 4**). The various modalities are discussed below:

### Physiotherapy

It involves repetitive exercises directed at a specific muscle group with a joint above and below (**Figs 8A to D**). This should be done

**Figure 6** Spastic hemiplegic cerebral palsy: note the asymmetry of position of right upper limb with flexion at elbow joint and slight flexion and splaying of fingers. The child is standing with legs wide apart  
Source: Dr Srishti Goel.

at least thrice a day with complete range of movement. It also includes the equipment required to develop strength and motor skills required in sitting, standing, balancing, etc., and control of

**Table 5** Components of an in-depth evaluation of a child with cerebral palsy

Component	Salient aspects to be evaluated
History	Parental concerns (presenting complaints) Motor manifestations Comorbid conditions Bladder and bowel habits Dietary and water intake and feeding Developmental history: all domains Histories pertaining to etiology (antenatal, natal, postnatal) Family history (3° pedigree tree)
General physical examination	Anthropometry especially for microcephaly, wasting and stunting Dysmorphology Neurocutaneous markers Amiel-Tison angles (by a goniometer) Orthopedic complications (joints, spine)
Extended neurological examination	Posture, alertness and interest in surroundings Cranial nerve examination Observe posture and gait Observe movements: range, symmetry, abnormality Tone: feel muscles, shake limbs, observe resistance to passive movements Reflexes
Developmental examination	Developmental maneuvers Cross check accuracy of developmental milestones elicited
Assessment of oromotor function	Interference of primitive reflexes with feeding Tongue weakness, tongue thrust and jaw thrust Difficulty in closing mouth, sucking and swallowing Uncoordinated mandible and tongue movements Tonic bite reflex Hyperactive gag reflex Neck hyperextension

movement (**Fig. 9**). The basic principle is encouraging movement that is as normal as possible, maintaining correct positioning in activities of daily living (ADL) and reducing inappropriate postures (**Figs 10A and B**). Recently the American Academy of CP and Developmental therapy stated that apart from decreasing abnormal joint motion and limiting contractures, physiotherapy (PT) had no long-term benefit for children with severe disease or beyond 4–7 years.

### Occupational Therapy

It includes instruction and use of techniques and adaptive equipment to develop skills required for ADL (**Figs 11A and B**). The aim is increasing functional skill and independence. Devices can be mobility-assistive like wheelchairs, crutches and customized orthoses (ankle-foot orthosis, knee orthosis, knee-ankle-foot orthosis). They can also be ADL-assistive like devices that enable feeding (cup handle, spoon handle), dressing (Velcro straps, zipper pull), grooming (adapted toothbrush, comb) and bathing (long-handled sponge). Feeding management is especially important and includes the use of shallow spoons, feeding of soft textured food or small pieces of solids with special techniques (placing food in the middle of tongue, applying pressure on the jaw while chewing to keep mouth closed to minimize tongue thrust and encourage swallowing, rubbing the gums before meals for perioral desensitization). Strategies to maximize arm and hand function in hemiplegic CP have been developed.

*Constraint-induced movement therapy (CIMT)* Movement of the affected side is constrained with casts so that the impaired limb is forced to perform under motivation repetitively. However, it proved to be frustrating and demotivating for the child and failed to address bimanual deficits and coordination defects.

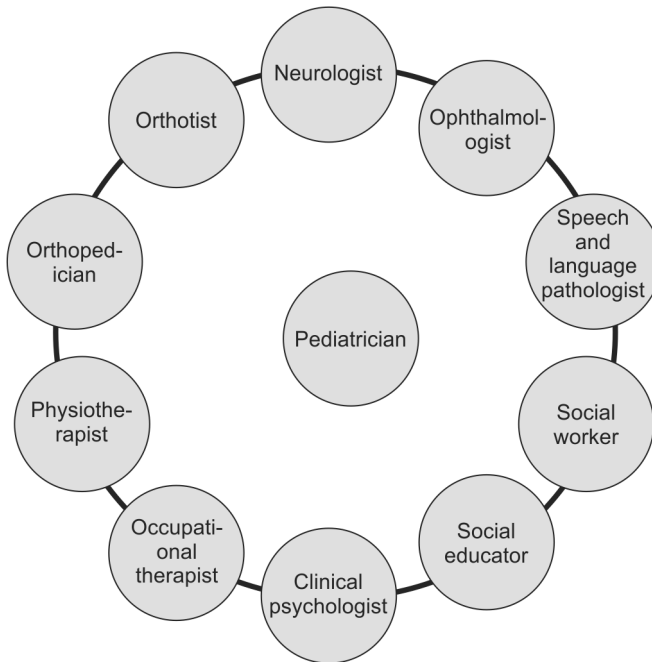

*Hand-arm bimanual intensive therapy (HABIT)* Bimanual coordination is improved by performance of bimanual activities without a physical restraint in a similar environment. The task is

**Table 6** MRI-topographic-etiology correlates in cerebral palsy (CP)

Topographic classification	MRI findings	Common etiologies
Diplegic CP	White matter damage of immaturity (WMDI): periventricular leukomalacia, posterior > anterior Periventricular cysts/scars in WM Enlargement of ventricles Squared posterior ventricles	Prematurity Ischemia Infection Metabolic
Quadriplegic CP	Cortical-subcortical lesions Extensive WMDI Multicystic encephalomalacia Cortical malformations	Ischemic injury Infection Endocrinal Metabolic Genetic/developmental
Hemiplegic CP	Asymmetric WMDI Stroke (in utero/neonatal) Focal infarct (cortical/subcortical) Cortical malformation	Thrombophilic disorder Infection Genetic/developmental PV hemorrhagic infarction
Dyskinetic CP	Basal ganglia lesions in different combinations Symmetrical scars in putamen and thalamus Scars in globus pallidus, hippocampus Scars in GP, putamen, caudate, brainstem No lesions	Severe birth asphyxia Kernicterus Mitochondrial Genetic/metabolic disorders

**Table 7** Differential diagnoses of cerebral palsy (CP) based on stage and type

Evolving CP	Established cerebral palsy			
	Spastic quadriplegic CP	Spastic diplegic CP	Extrapyramidal CP	Ataxic CP
Musculodystrophies (when predominantly motor delay) Global developmental delay (when $\geq 1$ domain affected)	Post-traumatic, atlanto-axial instability, neural tube defects, Pelizaeus-Merzbacher disease Peroxisomal disorders	Arginase deficiency, Hereditary spastic familial paraparesis, Juvenile metachromatic leukodystrophy	Primary neurotransmitter deficiencies, Dopa responsive dystonia, Primary dystonias, glutaric aciduria type I	Neurodegenerative causes of ataxia

**Figure 7** Members of a multidisciplinary team involved in management of cerebral palsy

demonstrated to the child who is then encouraged to perform it with positive reinforcement. If the child tries to compensate with the unaffected extremity, the activity is stopped and the process repeated.

### Speech Therapy

Parents are instructed on how to: (1) provide a stimulating environment conducive for speech and communication; (2) help in exercises for improving muscle tone of tongue and throat that result in decreasing drooling; and (3) dealing with feeding problems. Communication can be augmented with technologically advanced devices like specialized keyboards, talking typewriters, electronic speech-generating devices and specially adapted computers.

### Management of Spasticity

Indications of treating spasticity include impairment in muscle function, pain, secondary orthopedic complications or interference in care. This is achieved by the following:

**Physical therapy** Night splints and orthotics provide passive stretch.

**Drugs** The practice parameter for pharmacological treatment of spasticity in CP recommends botulinum toxin A for localized spasticity and considers diazepam and tizanidine for short-term treatment of generalized spasticity. It states that there is

insufficient data to support or refute the use of phenol, alcohol, or botulinum toxin B in the former and for dantrolene or baclofen (oral/intrathecal) in the latter. Details of drugs are given in **Table 8**.

**Surgery** Selective dorsal rhizotomy is a laminoplasty of L1-S1 with selective section of 20–40% of the dorsal rootlets. Indications include pure spasticity, good selective motor control, adequate muscle strength, 4–7 years age and spastic diplegia. Long-term complications have caused it to fall into disrepute.

**Age-dependent planning of spasticity reduction** PT or botulinum toxin A is preferred for children less than 4 years. Between 4 and 7 years options include management of generalized spasticity. Beyond 7 years the development of severe *lever arm disease* or contractures make these modalities redundant.

### Other Drugs

**Abnormalities of tone or motor movements** Levo-dopa (0.5–2 mg/kg/day), carbamazepine and trihexyphenidyl (0.25 mg/day, BD-TDS) have been used for dystonia. Tetrabenazene (12.5–25 mg/day, BD-TDS), neuroleptics and benzodiazepines have been tried for choreoathetosis, which is difficult to treat.

**Drooling** Anticholinergics like oral glycopyrrolate or transdermal scopolamine may be used if occupational therapy (OT) exercises fail but are limited by side effects (constipation, urinary retention). Local botulinum toxin A in both submandibular and parotid glands has been tried with success.

### Physical, Visual and Hearing Rehabilitation

Hearing and visual aids need to be provided as needed. **Orthopedic management** should be aimed to prevent deformities, improve function and relieve pain.

**Correct muscle imbalance** This can be noninvasive (passive stretching, night splinting, serial casting, localized reduction in spasticity) or invasive (heel-cord tightening, surgical lengthening, tendon transfers).

**Contractures** When dynamic (movable on passive stretching) PT is beneficial, once fixed (immovable) soft tissue release or tendon lengthen without weakening.

**Reconstructive surgery** This is resorted to for restoring muscle balance, releasing contractures and stabilizing joints to improve placement of the hand in space, voluntary grasp, release and pinch functions.

**Corrective surgery** This is required for the 'bony lever disease' described earlier. It is crucial that the individual components are correctly identified. Secondary abnormalities need to be rectified. Interference with tertiary abnormalities results in worsening of function. The **Video Gait Analysis** is an optoelectronic computer-based system that objectively analyzes gait and documents joint movements in multiple planes and levels. It is particularly helpful in preoperatively determining cause of crouch gait (equines/hamstring tightness, lever arm dysfunction), in-toeing (femoral

or tibial torsion), and pes varus (anterior or posterior tibialis dysfunction).

*Orthopedic selective spasticity control surgery (OSSCS) or single event multilevel surgery (SEMLS)* It refers to correction of all deformities (soft tissue and bony) in one hospital admission, requiring single exposure to anesthesia and rehabilitation. Multiarticular muscles

**Figures 11A and B** A customized corner chair to facilitate the sitting position: (A) with a table for promoting eye-hand coordination and hand activities; (B) with a wedge to keep both lower limbs apart  
Source: Dr Srishti Goel.

with limited antigravity action are selectively released and monoarticular antigravity muscles are preserved. The best age for surgery is 4–6 years for lower limb surgery and 6–8 years for upper limb surgery. Unstable lever arm disease must be operated irrespective of age.

### Other Surgical Indications

This includes surgeries for refractory drooling (salivary duct ligation), GERD not amenable to medical management or gastrostomy/jejunostomy for feeding when there is significant malnutrition and failure to establish adequate feeding.

### Dietary Advice

Young children with malnutrition should be given calorie-dense, balanced semisolid diet in small quantities frequently. If older and nonambulatory with adequate nutritional status, calories should be restricted to ~65% to avoid obesity. Adequate water intake should be ensured. Constipation should be treated with fluids, stool softeners, specific PT for increasing bowel motility

and adaptive toilet seats. Micronutrient supplements should be given.

### Special Education

This involves planning of flexible instructional programs based on individual strengths and weaknesses. This employs strategies aimed at developing sensory and perceptual motor skills, language, cognition and memory with reinforcement of learning. They also teach socially acceptable behavior and provide academic instruction in a stimulating learning environment.

### Educational Placement

Children with normal intellect should attend regular schools. Those with borderline intelligence or mild impairment benefit from integrated schooling. Others require special schools and vocational training. Educational placement of children with disabilities is mandatory by Indian law. Institutions are supposed to be equipped with facilities like ramps, lifts, adaptive toilets, etc. Like any other teenager, these children need to be prepared for the various changes and emerging sexuality that occurs during this period.

### Advocacy and Parent Support Groups

Emotional support for the family is important for successful management. Looking after children with CP is stressful and distorts family dynamics. Social workers can help in easing difficult situations and strain on families. Parents should be made aware of parent support groups, disability benefits and the *National Trust for the Welfare of Persons with Autism, CP, mental retardation and Multiple Disabilities Act, 1999*. The latter mandates that all children should receive equal opportunities, protection of rights and full participation in education, employment and others.

### Parental Counseling

Relevant information should be explained sensitively as per the parent's level of understanding. It may take more than one sitting. It is essential to empathize and be realistic without being fatalistic or giving false expectations. In nontechnical language parents need to be counseled about the nature, pathogenesis, comorbid conditions and natural course of CP. Feelings of personal guilt should be

**Table 8** Drugs used to reduce localized and generalized spasticity

Indication	Drug	Mechanism of action	Route	Dose	Side effects
Localized spasticity	Botulinum A toxin	Prevents presynaptic release of acetylcholine at neuromuscular junction	IM, repeated every 4–6 months	Small muscle 1–2 U/kg, large muscle, 4–6 U/kg each Limited to 12 U/kg or a maximum of 400 U per visit	Unwanted paralysis of adjacent muscles, swallowing difficulty, pain, rash, malaise
	5% phenol	Temporary neurolytic agent	Direct into obturator/musculocutaneous nerves	Variable 1–3 mL per nerve	Requires electrical stimulation Lethal if > 8 mg/day
Generalized spasticity	Diazepam	Facilitates GABA-A receptor-mediated presynaptic inhibition	Oral	0.5–0.75 mg/dose, BD-QID	Sedation, tolerance, withdrawal seizures
	Tizanidine	Central alpha-2 noradrenergic agonist	Oral	0.3–0.5 mg/kg/day QID	Dry mouth, somnolence, dizziness, asthenia
	Baclofen	GABA-B agonist	Oral	0.2–2 mg/kg/day BD/TDS	Seizures, headache, urinary retention, insomnia
			Intrathecal	Implanted pump	Constipation, urinary retention, CSF leak, infection
	Dantrolene	Muscle relaxant	Oral	0.5–10 mg/kg/day BD-QID	Sedation, CNS effects, GIT effects

identified and addressed appropriately. Treatment options need to be discussed. It should be emphasized that although not curable, CP is definitely treatable and with appropriate intervention the quality of life can be good. The need for compliance and regular follow-up requires highlighting. At first, contact proper counseling can make a child (parents understand the situation, are willing to start intervention, comply with instructions and come for follow-up) while improper counseling can break a child (parents feel that the situation is hopeless and nothing can be done; so they do not even try).

## MANAGEMENT IN RESOURCE-CONSTRAINED SITUATIONS

The management outlined previously is considered ideal. If such dedicated multidisciplinary centers are not available, pediatricians should ensure that management remains family-centered, competent, comprehensive, compassionate, continuous and community-based. In addition to routine pediatric issues, they must assume the role of team coordinator and counselor. To achieve this, they need to follow the guidelines given below:

1. Have a referral list of competent service providers and establish open communication channels with them. After referral, a management plan can be devised as outlined earlier with their inputs.
2. Discuss treatment options with parents and plan a feasible schedule by categorizing modalities as frequently required (i.e., OT, PT and speech therapy) and not so frequently required (hearing, visual and orthopedic) so that parents feel that it can be adhered to.
3. Determine whether they have understood the therapist's instructions by checking questions and asking them to demonstrate.
4. Advise regarding domiciliary management that can supplement the above. A pediatrician should have working knowledge about the following:
  - i. Proper handling and positioning during ADL. This should be taught to all family members so that caregiving can be shared (**Table 9**). Emphasize avoidance of vigorous oil massages.
  - ii. Providing a stimulating environment. These include use of bright colors, different textures, different voices, exposure to various experiences and people.
  - iii. Promoting speech and communication. These include repeated naming of common objects in the immediate environment. Use simple, direct and brief language that the child understands. Indulge in shared attention activities like looking at picture books with naming. Immediately mimic whatever sound or word the child utters to promote vocal reciprocity.
  - iv. Encourage play in different positions and with other children. Practice holding and releasing toys. Encourage use of both arms and separately.
  - v. Handle behavioral issues like temper tantrums appropriately and consistently. Do not be indulgent simply because the child has a chronic disorder.

## OUTCOME

Understandably, children with CP have higher mortality and morbidity due to various health issues. Poor prognostic factors are spastic quadriplegia, apparent motor delay within 6 months, persistent primitive reflexes by 2 years, inability to sit by 4 years and inability to walk by 7 years. Good prognostic factors include spastic diplegia, head balance in prone position by 9 months, sitting by 2 years, crawling by 30 months, access to early intervention, good family support and absence of comorbidities.

## PREVENTION

**Primary prevention** Improvement in healthcare in antenatal period (supervised pregnancies), during delivery (more trained birth attendants or hospital deliveries, improvement in transport facilities, administration of predelivery steroids in preterm labor, monitoring of high-risk newborns) and neonatal period (educating mothers about personal hygiene and exclusive breastfeeding, discouraging prelacteals, teaching danger signs and promoting healthcare seeking from qualified doctors).

**Secondary prevention** This entails increased sensitization of pediatricians with training in developmental screening and surveillance and implementation of these into the health services so that high-risk children get detected early and timely intervention is started.

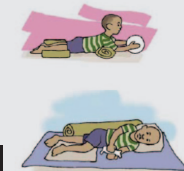

### IN A NUTSHELL

1. Cerebral palsy is the most common cause of chronic motor disability in childhood.
2. Essential criteria that define an intrapartum event sufficient enough to cause CP are metabolic acidosis umbilical cord arterial blood, early onset of moderate or severe neonatal encephalopathy in babies greater than or equal to 34 weeks' gestation, spastic quadriplegia or dyskinetic CP and exclusion of identifiable causes.
3. Hypoxic injury at birth is responsible for less than 10% of cases of CP.
4. Every child with CP requires a detailed history and examination and diagnosis is essentially clinical.
5. Cerebral palsy is characterized by decreased motor power in the presence of abnormal tone, gait, limb positioning, movements and reflexes.
6. The role of investigations is to determine etiology, assess comorbid conditions and assess complications.
7. The final diagnosis should be multiaxial encompassing physiological, topographic, ICF/functional and neuroradiological classification, etiology, timing of insult, comorbid conditions, complications and nutritional status.
8. Evaluation and management should be by a multidisciplinary team (rehabilitative, medical and surgical).
9. Management needs to be family-centered, competent, comprehensive, compassionate, continuous and community-based.
10. Parental counseling is crucial. The first contact interaction can make or break a child.

## Chapter 21.1

### Moral Development

Prahbhjot Malhi, Rajalakshmi Iyer

Moral development plays a significant role in child's life as it lays the foundation for social interactions and helps children adapt to the standards in their environment. The Oxford dictionary defines morality as *principles concerning the distinction between right and wrong or good and bad behavior*. According to Turiel (2002) morality refers to issues of human welfare, justice, and rights that are a function of the inherent features of interpersonal relations. While these definitions hold good for all societies, one needs to distinguish between morality and social conventions and norms. Social conventions and norms are culture dependent and can alter the interpretation of morality. However, it is important to keep in mind that morality is more universal and cuts across cultures.

#### THEORIES OF MORAL DEVELOPMENT

Moral development actually begins very early and is greatly influenced by parenting styles and highly susceptible to modification by the social milieu the child grows in. Moral values include sharing, cooperation, moral reasoning, empathy and autonomy. These values develop over the years in children and these are influenced by home, school and the neighborhood. Children tend to parallel their parents' actions with respect to moral judgment, and are also influenced by their teachers, the books they read and the outlook of their peer group. For most societies, concern and caring for others, empathy, justice and self-control are important social and moral values and efforts are made to inculcate these values in individuals. Many theorists have attempted to explain how moral development takes place in children and a brief description of the important child development theories is presented below.

#### Piaget's Theory

Jean Piaget was the first theorist to systematically examine moral development in children. Piaget conducted interviews with 5–13 years old children by presenting stories in which characters' intentions about right and wrong actions and the consequences about their actions varied. For example, children were asked which of the two boys was wrong: the one who broke more cups unintentionally or the one who broke fewer cups, but intentionally. According to Piaget, there are two broad stages of moral development. The first stage, heteronomous morality characterizes the thinking of 3–10 years old, wherein children view rules as determined by an external authority like the parents, teachers and God. Younger children accept rules from authority figures without questioning as they have limited cognitive capacity. In this stage, the child who broke more cups, regardless of intention, is judged to have performed a greater transgression. As children grow older,

and mature cognitively they move to the autonomous stage of moral development. In this stage, children do not view rules to be externally determined or universally applicable but rather perceive them as flexible and socially determined. Older children are also more likely to take another person's intent into consideration before making a judgment. Piaget also emphasized the role of peer disagreement in developing perspectives on moral actions. Piaget's theory has been subjected to considerable empirical scrutiny and many authors have found support for his contention that moral understanding is related to children's cognitive development.

#### Kohlberg's Theory

According to Lawrence Kohlberg, children learn their moral values through active thinking and reasoning and moral development follows a series of stages. Children pass through three stages in developing their sense of justice and in the kind of reasoning they use to make moral judgments: (1) the preconventional level, (2) the conventional level, and (3) the postconventional level (**Table 1**). Each of these stages is further divided into two stages.

Kohlberg developed his theory of moral development by presenting a series of hypothetical moral dilemmas to the participants and asked them what the main actor should do and why. Based on their reasoning, respondents were scored on a moral judgment scale to determine their stage of development. The most commonly quoted of these dilemmas was **The Heinz dilemma**:

*In Europe, a woman was near death from a special kind of cancer. There was one drug that the doctors thought it might save her. It was a form of radium that a druggist in the same town had recently discovered. The drug was expensive to make, but the druggist was charging 10 times what the drug cost him to make. He paid \$200 for the radium and charged \$2,000 for a small dose of the drug. The sick woman's husband, Heinz, went to everyone he knew to borrow the money, but he could only get together about \$1,000 which is half of what it cost. He told the druggist that his wife was dying and asked him to sell it cheaper or let him pay later. But the druggist said: "No, I discovered the drug and I'm going to make money from it." So Heinz got desperate and broke into the man's store to steal the drug for his wife. Should the husband have done that?*

#### Level I: Preconventional level (Toddlers—2–3 Years)

**Stage 1—The preconventional level** The punishment and obedience orientation: The child judges what is right and wrong based on the physical consequences of one's actions. If one is punished for an act then it viewed as bad, and acts which are rewarded are perceived as good. This is the most immature level of moral reasoning, because it is characterized by an egocentric emphasis and external determination.

**Stage 2—The instrumental purpose orientation** In this stage, the child views right actions as determined by self-interest. Anything which benefits the child is considered good. The needs of others are very rarely considered in this stage of development, unless they help the child in some way.

## Level II: Conventional Level (Preschool Years—3–6 Years)

*Stage 3—Interpersonal concordance orientation or the good boy, nice girl stage* The child now begins to care about what others think and approval by others becomes important. Obeying social rules, meeting social expectations and maintaining order is considered being moral.

*Stage 4—The social law and order orientation (school years: 7–11 years)* Now, the child begins to think of society as a whole. The maintenance of law and order and a need to maintain a stable social structure shape moral values. Personal gain is considered inferior to what would benefit society as a whole; doing one's duty, respecting authority and keeping up social order take precedence.

## Level III: Postconventional Level (The Autonomous Stage)

The postconventional stage is considered the only truly mature stages of moral reasoning as it is detached from socially dictated rules and focuses on personal principles.

*Stage 5—The social contract-legalist orientation* At this level, personal values and opinions of others begin to gain a place in thinking. While the legal point of view retains its importance, scope for argument outside of it begins to make sense to the child. Although law may be binding, it may need modification to benefit the society as a whole. Justice begins to emerge as an important concept at this stage of development.

*Stage 6—The universal ethical principle orientation* This is the highest stage of morality and characterizes the values and thinking of great philosophers and individuals like Mahatma Gandhi, Martin Luther King and Mother Teresa. It comprises the belief that all people are created equal and that no law which gives justice to one and discriminates against another, is right. There is respect for the basic dignity of all people.

These stages occur in a defined order of transition and one has to pass through a lower stage to reach a higher one. Ordered acquisition of the stages of moral development has been demonstrated in research employing both longitudinal and cross-sectional designs. Additional evidence for the sequential acquisition of moral judgment stages is the strong positive relationship found between moral stage and age. The sequence of development is invariant and children cannot reach the highest level until about age 13 years—primarily because of limitations in cognitive development before that age. In fact, Kohlberg found that only a relatively small percentage of adults rise above the second level of his model and very few people reach the highest level of moral reasoning. Children in industrialized societies move through Kohlberg's moral stages more rapidly than children from nonindustrialized countries.

Moreover, strong cultural differences may emerge of what one considers moral. Indians have been found to be more concerned with issues of care and gave greater priority to interpersonal responsibilities than Americans who in turn are more concerned

with moral rules and issues of justice. Studies show that differences among cultures arise from different moral codes where Indians give priority to social duties, while Americans give priority to individual rights and personal choice. Moreover, Indians perceive interpersonal responsibilities as duties, while Americans see them as more voluntary.

Although Kohlberg's theory contributed substantially to the understanding of moral development, the research support is equivocal. One difficulty with the theory is that knowing right from wrong does not mean that individuals would act in accordance with their moral judgments. Moreover, the theory applies primarily to Western society and cross-cultural research suggests that Kohlberg's theory may not be universally applicable. Some authors, particularly Carol Gilligan, have criticized Kohlberg's moral development theory as being male orientated as it overemphasizes rights and justice which are typically masculine ideals and underemphasizes care and responsiveness which are typically feminine ideals. Although Kohlberg's theory has been revised since it was first published, it still remains one of the most accepted of all theories of moral development and remains the dominant theory in child development literature. The theory of Kohlberg has also been subjected to considerable scrutiny and other models have also been proposed as alternatives, which have endeavored to resolve some of its shortcomings.

## INFLUENCES ON DEVELOPMENT OF MORAL REASONING

### Child-Rearing Practices

Parents can facilitate or impede their child's moral development through role modeling and use of appropriate disciplinary methods and child-rearing practices which combine parental warmth, responsiveness and inductive discipline. Parents who narrate stories with moral implications and engage children in moral discussions encourage the development of morality and prosocial behavior. Parents who consistently use explanations that emphasize taking others' perspective, consequences of one's actions on others in their child-rearing are more likely to inculcate empathy, perspective taking and increased internalization of moral values in their children. Moreover, parents who listen to their children's opinions of moral dilemmas considerably increase their children's moral reasoning ability.

On the other hand, power assertive discipline such as using threats, shaming children and withdrawal of love tend to focus attention to external social expectations and development of morality based solely on fear of external punishment. Physically abused and neglected children engage in more stealing, cheating and show fewer rule compatible behaviors. Maltreated children may also have difficulty in understanding reasons for the morally inappropriateness of their behavior which may result in rigidity in the application of moral rules. Interestingly, evidence indicates that South Asian parents are more likely to use shaming, withdrawal of

**Table 1** Kohlberg's stages of moral development

Level	Stage	Definition
1. Preconventional	Obedience and punishment	Whatever leads to punishment is considered wrong; hence, children avoid punishment and seek out rewards
	Individualism and exchange	Right behaviors are those that are in the best interest of oneself
2. Conventional	Interpersonal relationships	Children believe that holding to social norms is being good
	Authority and social order	Law and order are considered the highest ideals
3. Postconventional	Social contract	At this stage, individuals start to use abstract reasoning to justify behaviors. Moral behavior is based on ethical principles that are comprehensive and universal such as justice, dignity and equality
	Universal principles	Develop internal moral principles

love rather than induction and reasoning as disciplining techniques in their child-rearing practices. Such parenting practices may actually hamper the acquisition of higher moral development in Indian children. Evidence also indicates that Indian children hold obligations to parents as far more important than other moral transgressions. Such findings raise questions about the cultural relevance of the highest stages of Kohlberg's moral development.

### Schooling and Peer Influences

Education has a strong impact on moral development and moral reasoning mainly because it introduces children to social, political and cultural issues which extend beyond personal issues. School also provides children immense opportunities to interact with diverse social groups and participate in academic discussions which encourage perspective taking. In fact, low school attainment, low intelligence and delayed moral judgment are all risk factors for juvenile delinquency.

Peer interactions during the formative years also play an important role in the development of moral reasoning, particularly during adolescent years. Close friendships provide the youth with increased opportunities for mutual perspective taking and enhances moral reasoning. Peer conflict and resolution of conflict with emphasis on compromising and negotiating is particularly important for development of moral reasoning in children.

### Culture and Morality

Moral values, religion and culture are the foundations of Indian society. Initially, the child's moral values closely parallel those taught to him, but with age, children tend to reason out what they believe is just and moral, and why. Evidence indicates that by the preschool years, children across cultural groups and social classes can differentiate moral transgressions, involving harm and unfairness, from social conventions, judging the former to be wrong regardless of external authority and punishment. However, cross-cultural studies have also shown that individuals from traditional cultural settings such as Arab villages and rural Nigeria are relatively reluctant to change their social conventions. Marked cultural differences between Asian and western cultures have been observed in several studies. Indian compared to Americans have been reported to be more oriented toward issues of care and interpersonal responsibilities, while Americans are more concerned with moral rules, issues of justice, individual rights and formal moral obligations. Tangible improvement in Indian children's social, emotional and moral behavior and ability to listen to another's argument have been noted by researchers who have attempted to enhance children's sociomoral reasoning and behavior of Indian children through intervention sessions.

### Implications for Parents and Pediatricians

Parents often turn to pediatricians for help in managing their children's behavioral and emotional problems. Parents actively seek guidance regarding the kind of parenting that can effectively foster positive outcomes in their children, including early internalization of societal values and norms. Thus, it is important for pediatricians to promote positive child-rearing practices that facilitate empathy, perspective taking and moral reasoning. **Box 1** presents some strategies for parents and other stakeholders to guide the moral development of children.

#### BOX 1 Strategies to teach morality to children

- Caregivers need to provide reasonable and rational reasons for rules
- Engage children in conflict resolution which emphasizes perspective taking, negotiation and compromise
- Provide opportunities for discussions which highlight understanding of different viewpoints
- Use positive disciplining techniques
- Encourage participation in youth activities that directly teach concern for others, engage in moral discussions
- Teach children self-control by delaying gratification, resisting temptation and setting limits to behavior.

#### IN A NUTSHELL

1. Moral development begins very early and is greatly influenced by parenting styles and highly susceptible to modification by the social milieu the child grows in.
2. According to Lawrence Kohlberg, children learn their moral values through active thinking and reasoning and moral development follows a series of stages. Children pass through three stages in developing their sense of justice and in the kind of reasoning they use to make moral judgments: (1) the preconventional level, (2) the conventional level and (3) the postconventional level.
3. Rearing practices, culture, morality, peers and schools all can influence the behavioral development of a child.

## Chapter 21.2

# Sleep Hygiene and Disorders of Sleep

Suresh Kotagal

Disorders of sleep are common in childhood. In a questionnaire survey of 332 children of 11 through 15 years of age, Ipsiroglu and associates observed that 28% of the subjects had snoring, insomnia, or a parasomnia. Occurrence of sleep problems in a high proportion of children in India has been documented in both urban and rural children and adolescents. Sleep disorders have a significant effect on the quality of life. Many are also treatable, which underscores the importance of prompt recognition and management. They are equally common in boys and girls. Sleep is also influenced by social and environmental factors, such as use of electronic media late into the night or illicit substance use.

## SLEEP: THE BASIC CONCEPTS

### Sleep Ontogeny

Sleep can be distinguished from wakefulness in a premature infant by 27–28 weeks' postconceptional age. At this age, 80% of sleep is of the active or rapid eye movement (REM) type. During early childhood, there is progressive reduction in REM sleep and a corresponding increase in non-rapid eye movement (NREM) sleep. Contrasting physiologic characteristics of the two types of sleep are shown in **Table 1**. Melatonin, a sleep inducing hormone, is produced by the pineal gland. It acts at the level of the suprachiasmatic nucleus of the hypothalamus to facilitate sleep induction and maintenance.

By 4–6 months of age, NREM sleep becomes fully differentiated into N1, N2 and N3 sleep—this corresponds respectively to light, intermediate and deep stages from the arousal threshold standpoint. The bulk of N3 occurs during the first-third of the night. Growth hormone release is closely linked to N3 sleep, with suppression of the latter leading to impaired growth hormone release.

The physiologic sleep-onset time in elementary school-age children is usually around 8:00 pm–8:30 pm. Around adolescence, there is a physiologic delay in sleep-onset time as it shifts to 10:30 pm–11:00 pm. As a result, they are unable to fall asleep at an earlier hour. When juxtaposed with the need to rise early for high school related activities, it is easy to understand why many teenagers are chronically sleep deprived and consequently show mood swings, impaired attention span, decreased reaction time and increased propensity for accidents.

## Sleep History

The key to evaluating sleep-wake disorders is a good history. The sleep history is provided by the patient, parent, or guardian. It is crucial in arriving at a specific diagnosis. Questions should pertain to:

- The sleeping environment (e.g., crib, bassinet, parent's bed)
- The sleeping position (e.g., prone or supine, semiupright)
- Habitual need for sleep aids (e.g., pacifier, rocking, patting)
- Time of entering bed, time it takes to fall sleep (sleep latency) and time of the final morning awakening (on school nights and during weekends and holidays)
- Sensation of restlessness in the legs before sleep onset, intrusive thoughts or worries that might interfere with sleep onset
- Presence of habitual snoring, mouth breathing, observed apnea, restless sleep, sweating, gastroesophageal reflux, scary dreams and behaviors at night suggestive of seizures or parasomnias
- Behavior during the daytime (irritability, inattentiveness, hyperactivity and sleepiness)
- Number of daytime naps and their duration (physiologic daytime napping is uncommon after age 4–5 years)
- Medications that may affect sleep-wake function (e.g., sedatives, stimulants)
- Interventions that the parents have used to improve the child's sleep
- In adolescents, one should also inquire about activities that might interfere with going to bed at a reasonable hour, such as after-school classes, vigorous exercise, heavy meals, caffeine, cell phones, computers, television, nicotine and illicit substance use late in the evening or close to bed time. Patients with restless legs syndrome may experience an urge to move their limbs, a feeling of *bugs or spiders crawling on their legs* in the evening hours, exacerbation of this discomfort when the limbs are kept still, and experience relief with movement. Daytime sleepiness assessment should include questions about taking involuntary naps in the classroom, automatic behavior, and the impact of sleepiness on driving, cataplexy, hypnagogic hallucinations, medications used to promote alertness, academic function and behavioral and mood problems, and the number of school days missed because of sleepiness.

## Sleep Related Examination

Height, weight and body mass index should be recorded because obstructive sleep apnea (OSA) may be associated with failure to thrive during infancy, and with obesity during adolescence (Arens et al., 2010). The blood pressure should be measured because long-standing and severe OSA can be associated with hypertension. OSA patients may exhibit craniofacial abnormalities such as chronic mouth breathing, micrognathia,

**Table 1** A comparison of rapid eye movement (REM) and non-rapid eye movement (NREM) sleep

Characteristic	REM sleep	NREM sleep
EEG pattern	Low voltage, fast frequencies	Higher voltage, slow frequencies
Chin EMG activity	Absent or intermittent	Continuous
Breathing pattern	Irregular	Regular
Brainstem respiratory response to rise in pCO <sub>2</sub>	Absent compensatory increase in minute ventilation	Preserved increase in minute ventilation
Dreaming	Present	Infrequent

Abbreviations: EEG, electroencephalogram; EMG, electromyogram.

dental malocclusion, macroglossia, myopathic face and midface hypoplasia, deviated nasal septum, swollen inferior turbinates and tonsillar hypertrophy.

## Diagnostic Procedures

### Nocturnal Polysomnography

Polysomnography is useful in evaluating intrinsic sleep disorders such as narcolepsy, OSA, nocturnal spells, periodic limb movement disorder. It consists of simultaneous monitoring of electroencephalogram (EEG), eye movements, chin and leg electromyogram (EMG), nasal pressure, thoracic and abdominal respiratory effort, electrocardiogram (ECG), and oxygen saturation, with synchronized video recording. This is accomplished using digital polysomnogram equipment that records and displays both fast biopotentials like EEG and EMG and slow biopotentials like oxygen saturation and respiratory effort/oronasal airflow (**Fig. 1**). PSG is facilitated by having the parents sleep in the same bedroom as the child as this helps to allay the child's anxiety. Children with Down syndrome, neuromuscular disorders and obesity may exhibit hypoventilation that is characterized by shallow chest and abdominal wall movement, with resultant CO<sub>2</sub> retention. It is therefore important to concurrently record end-tidal CO<sub>2</sub> levels as well. Criteria for the recording and scoring of sleep and sleep related events such as apnea, arousals and periodic limb movements have been published. The following are some common types of respiratory events:

**Obstructive sleep apnea** Loss of oronasal airflow or nasal pressure signal despite persistence of thoracic and abdominal respiratory effort, with 2–3% oxygen desaturation.

**Central sleep apnea** Simultaneous cessation of signal in the oronasal airflow and nasal pressure channels and thoracic and abdominal respiratory effort, with 2–3% oxygen desaturation.

**Mixed sleep apnea** Event initially appears like a central apnea, but there is recovery of chest and abdominal effort before oronasal airflow or nasal pressure signal. Mixed apneas have generally the same significance as OSAs.

### Oximetry

Sampling of oxygen saturation on an overnight basis is an approximate measure of sleep disordered breathing. The probe for oximetry is placed over a finger. The number of drops in oxyhemoglobin saturation by 4% or more are counted, along with baseline oxyhemoglobin saturation. The normal oxygen saturation is above 92%. The number of oxyhemoglobin desaturations below 92% is about 1/hour of sleep. If the desaturations are increased, this indirectly reflects sleep disordered breathing (central or OSA/lung disease). By correlating it with the clinical history, one can indirectly determine presence and severity of sleep disordered breathing (**Fig. 2**). Advantages of the overnight oximetry is that the test is inexpensive and can be conducted in the home environment. One disadvantage is that motion artefact may lead to suboptimal yield. Another limitation is that oximetry is relatively insensitive,

**Figure 1** Sample of nocturnal polysomnogram, during which electroencephalogram (EEG—Fz-Cz, Cz-OZ, C4-A1), chin electromyogram (EMG), leg EMG, electrocardiogram (ECG), oronasal airflow pattern, snoring, oxygen saturation, summation of rib cage and abdominal respiratory effort, rib cage (RC) motion and abdominal (Abd) wall motion have been recorded. This is a 30-second epoch. Note loss of oronasal airflow during an obstructive apnea episode (down arrowhead) despite persistence of abdominal respiratory effort. This is characteristic of an obstructive apnea episode. There is associated oxygen desaturation to 70%

**Figure 2** Overnight oximetry in a 6-year-old child with habitual snoring and severe tonsillar hypertrophy resulting in obstructive sleep apnea. Note recurrent episodes of drop in oxygen saturation below 90%. The desaturation episodes are most likely occurring during periods of REM sleep. The normal oxygen saturation value is one drop in oxygen saturation of 4% or more per hour of sleep. This patient shows 61 desaturation episodes, with oxygen saturation nadir of 86%. She was referred for tonsillectomy, with significant improvement in her symptoms

and may not pick up mild OSA, being positive only in about 25% of these children.

### Multiple Sleep Latency Test

The multiple sleep latency test (MSLT) assesses how quickly one is able to fall asleep during the daytime and whether transition from wakefulness is into NREM sleep or into REM sleep. It is used for assessing sleepiness in children aged 5 years and above. It consists of providing four daytime nap opportunities at 2-hourly intervals in a darkened, quiet environment, e.g., at 1,000 h, 1,200 h, 1,400 h and 1,600 h. The EEG, chin EMG and eye movements are monitored during each nap opportunity. At each planned nap opportunity, the lights are turned off and the patient is asked to try to sleep. The time from *lights out* to sleep onset is measured and represents the sleep latency. A mean sleep latency is also derived for the four naps. The nap opportunity is terminated either 15 min after successful sleep onset, or at 20 min after *lights out* if the patient does not fall asleep. The mean sleep latency decreases inversely with an increase in the Tanner stage of sexual development, and ranges between 12 min and 18 min (Carskadon, 1982). A mean sleep latency of less than 5 min indicates severe daytime sleepiness; a value between 5 min and 10 min indicates moderate daytime sleepiness. The occurrence of REM sleep within 15 min of sleep onset constitutes a sleep-onset rapid eye movement period (SOREMP). The presence of SOREMPs on two more nap opportunities in conjunction with a shortened mean sleep latency of less than 5 min is highly suggestive of narcolepsy.

Standards have been published for the conduct of MSLT in children.

## SPECIFIC SLEEP DISORDERS

### Apnea of Prematurity

**Epidemiology** This disorder of respiratory control affects 70–90% of premature infants. It may not be present initially at birth, but becomes manifest as the infant matures and is getting ready for discharge from the newborn nursery.

**Pathophysiology** Apnea of prematurity is likely multifactorial and related to immaturity of the structures that regulate respiratory control (ventral brainstem, carotid bodies and cardiorespiratory system). Gradual resolution of the disorder over time (by 48–50 weeks postconceptional age) supports this possibility.

**Clinical features** Patients may show mixed, central or obstructive apneas. There may be recurrent periods of apnea, bradycardia and oxygen desaturation.

**Differential diagnosis** Neonatal seizures, gastroesophageal reflux and structural upper airway lesions (e.g., unilateral choanal atresia) may need to be considered.

**Management** Caffeine citrate a methylxanthine can be used. The recommended dose is 20 mg/kg loading dose intravenously or orally, followed by 5 mg/kg/day by mouth or intravenous route. Improved long-term outcomes from the standpoint of cognitive and motor function have also been reported with caffeine use in the newborn period.

### Congenital Central Hypoventilation Syndrome

This disorder is characterized by defective automatic control of breathing during sleep. Patients generally become symptomatic at birth or shortly thereafter.

**Etiology** Congenital central hypoventilation syndrome (CCHS) is linked to mutations in the homeobox gene *PHOX2B*, which maps to chromosome 4p12, and is transmitted in an autosomal dominant manner. The gene encodes a highly conserved transcription factor. Approximately 92% of primary CCHS patients carry this mutation. About 20% of CCHS patients have coexisting Hirschsprung's disease. There is also an association between CCHS and neural crest tumors like ganglioglioma and neuroblastoma. Frameshift and missense *PHOX2B* mutations predispose to neuroblastoma. It has been postulated that CCHS is a neural crest disorder in which there is defective fetal development as brainstem neurons that regulate chemosensitivity are derived from the neural crest.

**Pathology** Common sites of hypoplasia or neurodegeneration include the arcuate nucleus of the medulla (regulates chemosensitivity), the ventrolateral nucleus of the tractus solitarius, nucleus ambiguus or nucleus retroambiguus, and the nucleus parabrachialis in the dorsolateral pons.

**Clinical features** The respiratory rate and depth are initially normal during wakefulness, but shallow and infrequent breathing, hypercarbia, and oxygen desaturation occur initially during NREM sleep and then during REM sleep. The PaCO<sub>2</sub> is greater than 60 mm during sleep despite absence of pulmonary, neuromuscular or cardiac disease.

**Management** There is no definitive and satisfactory treatment, although acetazolamide and theophylline may enhance chemoreceptivity of the brainstem respiratory neurons. Diaphragmatic pacing and home ventilation via tracheostomy are other therapeutic modalities. Patients may die in infancy or early childhood.

## APPARENT LIFE-THREATENING EPISODES

**Epidemiology** These are defined as episodes that are frightening to the observer and characterized by a combination of apnea, skin color change, marked changes in muscle tone, choking and gagging. The disorder is most prevalent during the first 6 months of life. Apparent life-threatening episodes (ALTEs) are about 14 times more common in preterm infants than those born at full term.

**Etiology** No definite etiology is found in close to 40–50% of cases. Events occurring during wakefulness may be linked to gastroesophageal reflux. OSA, focal seizures, cardiac arrhythmias, congenital heart disease also need consideration.

**Clinical assessment** As with any episodic disturbance of bodily function, a detailed history is important. The body position in which the infant was placed to sleep (supine vs prone), the position in which the infant was found by the parent/guardian, the state of the infant just prior to the event (awake or asleep), presence of head segment automatisms like lip smacking or eyelid fluttering and tachycardia suggestive of seizures, duration of the event, whether or not resuscitation measures were needed and of what type; constipation, nonreactive pupils and weakness (suggestive of infantile botulism), history of gastroesophageal reflux, family history of sudden infant death syndrome, fever and lethargy (suggestive of sepsis), thermoregulation and sweating abnormalities (suggestive of dysautonomia), habitual snoring and mouth breathing (suggestive of upper airway obstruction) should be inquired about. Special attention should be paid to pulse, blood pressure, cardiac and respiratory examination, craniofacial abnormalities, external signs of trauma, mouth breathing, tonsillar hypertrophy, hypotonia, pupil size and reactivity, and motor activity and tendon reflexes.

**Investigations** The most common studies are EEG, magnetic resonance imaging of the head, ECG, echocardiogram, urinary organic acid assay and serum carnitine levels (to rule out medium chain acyl-coA dehydrogenase deficiency) and esophageal pH monitoring (to evaluate for gastroesophageal reflux). Hospitalization during this evaluation process is indicated as it provides the family some time to ask questions of the medical team, learn cardiopulmonary resuscitation techniques and collaborate with the health professionals in the discharge planning process.

**Outcome and management** The recurrence rate for ALTEs may be as high as 60%, with the second event generally occurring within a few days of the initial event. Ultimately there is spontaneous resolution over months. Parents should be familiar with cardiopulmonary resuscitations. Close follow-up is sometimes necessary.

## Obstructive Sleep Apnea

**Epidemiology** Obstructive sleep apnea is characterized by recurrent episodes of oxygen desaturation with simultaneously preserved thoracic and abdominal respiratory effort. Prevalence rate in Western countries is 2–4% of the general population. Habitual snoring, which is the mildest form of sleep related upper airway obstruction, has a prevalence rate of 8–10%. OSA is more common in those born prematurely. It is equally prevalent in boys and girls.

**Etiology** The most common causative factors are adenotonsillar hypertrophy, nasal allergies, exposure to passive smoke, neuromuscular disorders, and craniofacial anomalies like mid-face hypoplasia, retrognathia and macroglossia. Complex upper

airway problems such as unilateral choanal atresia, macroglossia, laryngomalacia, vocal cord paresis, laryngeal clefts, and tracheoesophageal fistula may be observed in infants. Obesity can be a factor in older children and adolescents. Some degree of inflammation and consequent upper airway edema are common and occur from increased vibration of the soft palate and uvula during sleep.

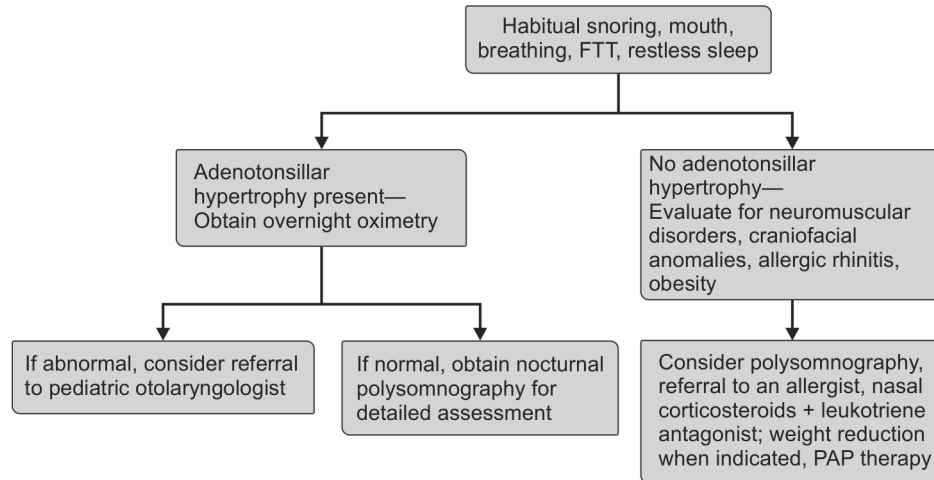

**Clinical features** Sleep is fragmented, with increased frequency of respiratory event related arousals due to episodes of oxygen desaturation. There may be tendency to breathe with the mouth kept partially open, and to manifest restless sleep, excessive sweating while asleep, nocturnal enuresis, sleep walking and waking up in the morning feeling tired. Sometimes an airway protective maneuver such as keeping the neck extended while asleep is observed. Note that infants with hypotonia and weak respiratory musculature do not consistently snore. During the daytime, there may be fatigue, mood swings, irritability and inattentiveness. Failure to thrive may occur in infants from increased energy expenditure for breathing.

**Investigations** Polysomnography is recommended as it helps to differentiate central from OSA, and also helps to assess the severity of OSA. If PSG is unavailable, utilizing overnight oximetry to document recurrent episodes of nocturnal oxygen desaturation is recommended (**Fig. 2**). A sleep specialist (ideal) or pulmonary specialist should be consulted. Patients with confirmed OSA should be seen by an otolaryngologist, and if possible, by an allergist. Direct visualization of the upper airway under anesthesia using flexible endoscopy allows for the detection by the otolaryngologist of areas of narrowing from the nasal passages down to the glottis. Environmental factors that predispose to nasal irritation, such as smoking by parents and relatives should be investigated.

**Management** Adenotonsillectomy is generally the first step in management. Those less than age of 3 years, craniofacial anomalies, or severe OSA should be monitored closely in the hospital for postoperative airway compromise from upper airway edema and swallowing difficulty. The cure rate following adenotonsillectomy varies from 30% to 70%. OSA may persist if there are predisposing factors such as anatomic upper airway abnormalities, obesity, neuromuscular disorders or persistent exposure to cigarette smoke. In case of persistent OSA, consideration is given to use of positive airway pressure (PAP) breathing. This is delivered using commercially available and licensed PAP devices that are connected to nasal or full face mask. The PAP splints the upper airway and thus maintains its patency while asleep. Mild OSA can be treated using a topical nasal corticosteroid combined with a leukotriene antagonist such as montelukast. Smoking parents should be strongly counseled about enrolling in a smoking cessation program. Please also refer to **Flow chart 1** for management guidelines.

## Narcolepsy

**Epidemiology, classification and pathophysiology** Narcolepsy is a primary central nervous system disorder of vigilance. It affects about 1 in 100,000 persons each year. About one-third of all patients with narcolepsy have onset of symptoms prior to the age of 16 years. A distinction is made between narcolepsy *without* cataplexy, and narcolepsy *with* cataplexy (NC). Some patients in the former category will eventually develop cataplexy 5–10 years after initial symptom onset. NC is characterized by positivity for histocompatibility antigen DQB1\*0602 and reduced levels of cerebrospinal fluid (CSF) hypocretin (Orexin). Recent studies implicate T-cell mediated immunity in pathogenesis, with very localized injury/loss of the hypocretin secreting neurons in the dorsolateral hypothalamus.

**Flow chart 1** Algorithm for management of obstructive sleep apnea

Abbreviations: FTT, failure to thrive; PAP, positive airway pressure.

**Clinical features** Hypersomnolence (excessive sleepiness) may be difficult to recognize. In a preschool or elementary school age child, it may manifest as resuming naps which the child had previously outgrown, mood swings and inattentiveness. Cataplexy (episodes of muscle weakness with laughter, anger, or surprise) may be fairly subtle, with only jaw dropping open or slight head roll. Hypnagogic hallucinations (vivid dreams at sleep onset) and sleep paralysis (inability to momentarily move the body at sleep onset); young children do not provide a reliable history of these symptoms. Obesity/overweight and precocious puberty is common in NC at the onset.

**Precipitating factors** These may include a flu-like illness, infectious mononucleosis, or streptococcal illnesses and are encountered in NC.

**Diagnosis** Polysomnography and MSLT are valid after the age of 5 years. Both tests may show sleep-onset REM periods. Further, the MSLT helps to document extreme daytime sleepiness. For younger children less than age of 5 years, one has to rely on documentation of low CSF hypocretin levels.

**Differential diagnosis** Sleepiness and fatigue as a consequence of depression or Kleine-Levin syndrome; use of illicit substances.

**Management** Planned naps at school or upon return home from school for 3–45 min are recommended. Provision of psychological support is very important, especially for teens owing comorbid anxiety and coping issues. Medications for excessive sleepiness include salts of methylphenidate/amphetamine/modafinil or armodafinil. The dosing may need to be 2–3 times per day for effectively controlling sleepiness. For cataplexy, the use of clomipramine/protriptyline, atomoxetine, or fluoxetine is recommended. Patients should be counseled about avoiding driving and use of alcohol. Patient and parents should be informed that narcolepsy is a lifelong disorder. Emotional support through psychological counseling should be provided whenever required.

## Insomnia

Children and adolescents can manifest sleep initiation or sleep maintenance difficulties, or both together. There is a general dissatisfaction about the quality of sleep. Refer to **Tables 2** and **3** for more information.

**Table 2** Some principles of sleep hygiene

Daytime	<ul style="list-style-type: none"> <li>• Try to awaken at approximately the same time, 7 days a week</li> <li>• After age 5–6 years avoid daytime napping</li> <li>• Light exercise in the morning or in the afternoon (not at night)</li> <li>• Avoid caffeine intake in the 2–3 hours before bedtime.</li> </ul>
Night-time	<ul style="list-style-type: none"> <li>• Turn off electronic devices about an hour prior to bed time</li> <li>• Spend the hour prior to bedtime reading your <i>comfort</i> book</li> <li>• Avoid excessive consumption of food or drink before bedtime</li> <li>• If you wake up at night to use the toilet, use only the night light.</li> </ul>

**Table 3** Etiology and clinical features in insomnia

Inadequate sleep hygiene	Use of caffeine, alcohol or nicotine, use of computers, cell phone and television at night; managed with counseling
Restless legs syndrome	Irresistible urge to move the limbs that is worse when legs are kept still, relieved partially by movement; serum ferritin may be low, i.e., below 30 µg/dL; autosomal dominant; treatment is iron supplementation, combined if necessary with gabapentin for a few months
Anxiety	Frequent nightmares, history of emotional trauma or family history of anxiety; both sleep initiation and maintenance difficulty; needs psychological counseling
Depression	Early morning awakenings, dysphoria; needs to see a child psychiatrist
Psychophysiological insomnia	Very concerned about sleep quality (performance anxiety), conditioned arousals, clock watching at night, sleeps better away from bedroom than in it. Restricting total time in bed and psychological counseling are recommended.

## Miscellaneous Entities

*The relationship between sleep and epilepsy* There is a bidirectional relationship between sleep and epilepsy. Sleep deprivation lowers the seizure threshold. Further, OSA increases vulnerability to seizures by leading to sleep fragmentation, which increases vulnerability to seizures. It is a good idea to evaluate patients with poorly controlled seizures for comorbid OSA. Phenytoin can cause lymphoid hyperplasia, including adenotonsillar hypertrophy, that can lead to OSA.

*The relationship between sleep and headache* Sleep deprivation makes patients more vulnerable to breakthrough migraines. The routine counseling of migraine patients should include a discussion about sleep hygiene.

*The relationship between sleep and psychiatric disorders* Frequent nightmares are sometimes marker for underlying anxiety. Also, depression can be associated with insomnia. It is also well known that insufficient sleep contributes to daytime irritability and mood swings. It is a good idea to incorporate sleep hygiene into management of emotional and mood problems of children and adolescents.

### IN A NUTSHELL

1. Problems of sleep-wake function are very common in childhood. Their recognition and treatment can have a significant impact on the quality of life of the child.
2. It is important to incorporate sleep related history and examination into the clinical assessment of children.
3. The prevalence of obstructive sleep apnea (OSA) in infants and children in India is likely underestimated.
4. Adenotonsillar hypertrophy is the most common cause of childhood OSA, followed by craniofacial anomalies, neuromuscular disorders and obesity.
5. Infants with OSA may not snore.
6. Overnight oximetry can be used as a screening tool for severe OSA.
7. Inadequate sleep hygiene is the most common etiology for sleep initiation and maintenance difficulty in adolescents.
8. Causes of excessive daytime sleepiness include inadequate sleep hygiene, depression, drugs, obstructive hypoventilation, narcolepsy and Kleine-Levin syndrome.

## Chapter 21.3

# Common Behavioral Problems

Praveen Suman

Emotional and behavioral problems are seen commonly during the period of growing up and are due to the stress of development and adaptation to family expectations. These problems are among the most common reasons that children are seen by pediatricians. The age of occurrence of various behavioral problems has been explained on the basis of the *transactional model of development* as the specific problem depends on the developmental phase of the child around that age.

Around 12% children attending pediatric outpatient clinics meet the diagnosis of behavioral and emotional disorders. Worldwide, the community prevalence has been reported to range from 12% to 25%, though Indian studies report a wide range of 2.6–35%. These disorders often lead to distress to the child and family. To help the family, it is important to assess the magnitude of the problem, and identify and address underlying factors causing these problems. Along with the specific interventions, the most critical component is reassuring the parents, as majority of these are transient in nature. However, failure to address these problems may lead to repeat hospital visits, increasing cost, and academic, social, family and economic problems. This chapter provides an overview of common behavioral problems and interventions to manage them (Table 1).

### INFANTILE COLIC

When otherwise healthy infants cry intensely for an excessive duration, they are often referred to as having colic. The time spent crying progressively increases to a mean of approximately 2.5 hours/day during the 2nd month of life and decreases gradually thereafter. The diagnosis of colic requires that the child be otherwise healthy and feeding well. The amount of crying required for a diagnosis of colic is: paroxysms of crying for more than 3 hours a day for more than 3 days/week for more than 3 weeks. Infantile colic is diagnosed only when the baby is otherwise physically healthy and feeding well. Paroxysms are accompanied with facial grimacing, drawing up of legs, arching of back and sometimes passing flatus. The incidence of infantile colic is reported to vary from 5% to 19%, affecting girls and boys equally, and in all ethnic groups and socioeconomic classes.

### Etiology

The etiology of infantile colic is not known but physical problems that can cause excessive crying must be excluded prior to diagnosis of infantile colic.

A number of chronic conditions have been proposed to be the cause of infant colic including cow's milk allergy, lactose intolerance, constipation and gastroesophageal reflux; even though, controlled studies using interventions targeting these problems have not been found to be effective for most infants.

Differences in the temperament of infants with excessive cry from those who cry less have been reported; parents tend to rate these infants as more intense and more difficult to soothe. It has been seen that infants with persistent crying have higher crying-to-fussing ratio than those with less crying. When sucrose solution is administered orally to soothe an infant, the response is poor in infants with colic as compared to those without colic.

### Differential Diagnosis

In a crying infant, before considering the diagnosis of infantile colic, organic conditions should be excluded including infection (especially acute otitis media, meningitis, hidden boils in flexural areas/scalp), corneal abrasion, glaucoma, skull or long bone fracture, incarcerated hernia, supraventricular tachycardia, hair tourniquet and intussusception. Detailed history and physical examination to evaluate for the above-mentioned problems is important. Based on the findings of physical examination, investigations should be done in the form of laboratory tests and radiological investigation. In infants where clinical examination reveals no abnormality, urine examination should be considered to rule out urinary tract infection. In majority of the cases, a close observation of the child during the episode helps in reaching the diagnosis.

### Management

It is important to reassure the parents that their child is healthy and help parents to understand their infant's temperament trait contributing to increased crying. Parents should be counseled that crying is the infant's way of communicating, and it is not necessarily a sign of pain or illness. Parents need to understand that these infants are more difficult to soothe, and thus even when the parent is providing what the infant wants, it may take many minutes before the infant stops crying.

Medications like phenobarbital, simethicone and dicyclomine are not of much use and should be avoided. It is also recommended to avoid soothing of child using excessive shaking, and usage of traditional products like herbal potions, *ghutti*, etc. Dietary changes for the baby (or the mother) are also not of any sustained benefit.

Infantile colic usually disappears by the age of 4–5 months.

### THUMB-SUCKING

Thumb-sucking can be defined as placement of thumb into the mouth for various depths. Thumb-sucking and finger-sucking can more generally be termed as digit sucking. This habit is a concern to specialists in various fields such as pediatricians, psychologists, dentists and speech therapists.

**Table 1** Salient feature of some common behavior problems

Disorder	Age at which considered		Differential diagnosis	Management
	Normal	Abnormal		
Infantile colic	4–5 months	-	Acute gastrointestinal conditions	Parental counseling
Thumb-sucking	1 year	After 5 years	Repetitive behavior	Psychotherapy and reminder therapy
Pica	1 year	After 2 years	In cases of persistence rule out underlying intellectual disability, autism	Parental counseling and multimodal management of associated medical problems
Rumination	-	At any stage	GER	Improve parent–child relationship
Temper tantrums	1–3 years	After 4 years	In cases of persistence rule out underlying intellectual disability, autism	Ignoring undesired behavior

During the 1st year of life, thumb-sucking is considered as normal and usually does not lead to long-term effects. It usually disappears by 3–4 years of age. When this habit persists beyond preschool it is considered as abnormal. This habit needs attention, as otherwise it may lead to dentofacial structure abnormalities.

Thumb-sucking occurs in 23–46% of children aged 1–4 years, but most desist by school-age. If it persists beyond 4 years of age, it is a concern as dental malocclusion, digital deformities, speech difficulties and emotional problems may be associated. Studies have shown the persistence of thumb-sucking in approximately 6% at the age of 11 years.

## Etiology

It can be due to either (1) psychological reasons—due to deep-rooted emotional factor like insecurities, neglect and loneliness experienced by the child; or (2) habitual—the child sucks the thumb as a habit.

## Types of Thumb-sucking

*Type A* Where whole digit is placed inside the mouth with the pad of the thumb pressing over the palate while at the same time maxillary and mandibular anteriors contact is present. This is the most common type and seen in almost 50% cases.

*Type B* In this type thumb is placed into the oral cavity without touching the vault of the palate while at the same time maxillary and mandibular contact is maintained. It is seen in almost one-third of children.

*Type C* Where thumb is placed into the mouth just beyond the first joint and contacts the hard palate and only the maxillary incisors but there is no contact with the mandibular incisors. This is also as common as Type B.

*Type D* Very little portion of the thumb is placed into the mouth. It is seen in 6% of children.

## Diagnosis

Diagnosis is mainly based on the history. Detailed history regarding the frequency, intensity and duration of the habit is to be taken. Enquire about the feeding patterns, parental care of the child and also about other habits. Clinical examination will reveal signs of chronic inflammation on the thumb.

## Treatment

Treatment of thumb-sucking should be considered after 4–6 years of age and when it causes dental problem, digital malformation, or distress to the child. If child is a willing partner, the treatment is more effective.

Psychotherapy is an important part of the treatment which also includes motivation of the child to stop the behavior, by positive reinforcement. Reminder therapy includes various methods which remind the child to stop thumb-sucking. It is of different types:

*Extra oral approach* Using bitter flavored preparation like pepper, quinine or asafetida on the finger.

*Intraoral approach* Orthodontic appliances, which can be removable type (like palatal crib or palatal arc) or fixed type (Upper lingual tongue screens). In resistant cases, fixed intraoral antithumb-sucking appliances are used.

## Pica

Pica is defined as persistent ingestion of non-nutritive substances without an accompanying aversion to food, at an age in which this behavior is developmentally inappropriate. This should persist at least for 1 month to be considered abnormal. It commonly includes

ingestion of dirt, clay, pebbles, chalk, paper, string, ashes, crayons and plastic objects. Ingesting sharp objects such as nails, screws or potentially toxic substances such as medicine, dishwashing fluid can lead to far more serious and potentially life-threatening consequences.

## Prevalence

According to some studies, 10–32% children in the age group of 1–6 years exhibit pica, although an Indian study reported 2% occurrence in those younger than 3 years. The early developmental habit of mouthing objects as an exploratory behavior disappears by 2 years of age. Mental disorders found to have persistent pica more commonly associated with them include pervasive developmental disorders, intellectual disability, schizophrenia, Kleine-Levin syndrome. Children who continue to eat non-food substances on a consistent basis after their 2nd birthday should be evaluated for pica, as well as the presence of developmental disability and a variety of medical conditions with the serious health risks that accompany chronic ingestion of nonfood substance.

## Etiopathology

Cause of pica is unknown. To describe this behavior various theories have been proposed:

*Cultural, ethnic and familial theory* In some cultures there is a custom of eating soil for different illnesses, e.g., morning sickness, which leads to the perception that there is nothing wrong with pica.

*Organic or nutritional theory* Some studies have shown that iron and zinc deficiency increase the craving for nonfood substances. These children get involved in pica to satisfy the craving. However, the prevalence of dietary and mineral deficiencies in children with pica is similar to those without this habit.

*Neuropsychiatric theory* There is a higher incidence of pica among children with many developmental disabilities. Pica is the most common eating disorder in children with developmental disability. It is most frequently observed in those with severe and profound intellectual disability. Children may learn to engage in pica because it provokes adult attention (*positive reinforcement*) or allows escape from a nonpreferred activity (*negative reinforcement*). Pica is also perceived as a sensory activity that the child experiences as stimulating or pleasant.

*Organic hypothesis* Pica may also be explained by this hypothesis whereby genetic disorders such as Prader-Willi syndrome increase the risk of ingesting nonfood substances. Anxiety disorders such as hysteria and obsessive compulsive disorder also have been implicated.

## Diagnosis

It is important to distinguish between stereotyped mouthing of objects by very young children who accidentally ingest them and pica as a behavioral disorder. There can be immediate and long-term effects on health due to pica. The potential for parasitic infections with sequelae of myocarditis, encephalitis and hepatomegaly, and brain damage by intoxicants such as lead from paints and mercury from paper is of immediate concern. Obstruction from an indigestible mass that may cause choking or perforate the stomach or intestine and result in peritonitis is also a possibility.

Except in circumstances involving children and adolescents with autism spectrum disorder and intellectual disability, most cases of pica are easily diagnosed from history from parents. Children may be afraid of disclosing pica because of embarrassment or fear of being punished.

## Management

Educating the parents and child about the dangers associated with placing objects in the mouth is the basic step. Along with this, close supervision of the child by the parents, and making sure that the home-environment is safe for the child are additional measures.

There is no specific medical treatment and the condition often remits spontaneously. Medical management is multimodal in nature. Investigations need to be individualized but may include complete blood count (especially eosinophil count), peripheral smear, serum electrolytes, liver function tests, iron and calcium studies and lead levels. An X-ray abdomen, barium studies or ultrasonography of the abdomen may be occasionally necessary to diagnose obstruction from parasites or bezoars.

Children with lead poisoning may require chelation therapy. Dietary supplements for mineral deficiencies like iron and zinc, if identified, should be addressed, although limited success has been seen in decreasing the behavior. Specific therapies for parasitic infection may be given when required. In cases of obstruction, surgery may be needed.

Multidisciplinary approach involving psychologist, social worker and developmental pediatrician may be required. Psychological interventions are done to modify the behavior. Various behavioral strategies have been described, and very rarely, external devices restricting placement of objects in the mouth may be required for resistant cases. Children with underlying anxiety disorder or obsessive compulsive disorder may need appropriate referrals and medications.

## RUMINATION

Rumination is regurgitation of food which is then partially or completely reswallowed or rechewed. The exact prevalence of eating disorders is not known. It is known that more than 25% of parents are concerned about their child's eating behavior.

## Etiology

Rumination is poorly understood but believed to be self-stimulatory. Infants often initiate rumination by inserting a hand into mouth. They may also bring up the food by thrusting the tongue to the back of the mouth or by contracting their abdominal muscles. It is often associated with child neglect.

## Management

Other causes of vomiting such as gastroesophageal reflux are an important differential diagnosis of rumination. Premature and neurologically fragile infants may require behavioral strategies to decrease overstimulation. The diagnosis of rumination is made by observation. Intervention for children with rumination requires increased nurturing with attention to the infant-caretaker relationship.

## TEMPER TANTRUMS

Temper tantrums are often defined as out of control behavior including screaming, hitting, head-banging and falling down and other violent display of frustration, usually occurring in children of 18 months to 4 years of age. These are emotional outbursts in response to unmet needs or desires in younger children or children with communication difficulty. In extreme case, they may be expressed by vomiting or biting. When the behavior occurs many times a day, lasting 30 min at a time, and is associated with aggression at school and home; it usually requires intervention.

Thus, it is important to find out the frequency, intensity and duration of the behavior.

Temper tantrums have been reported to be present in 22% of normally developing children. In 75.3%, these are present at the age of 3–5 years and, in 20.8% at 6–8 years of age, being least common at 9–12 years (3.9%). They are more common in boys.

## Etiology

Temper tantrums are natural during early childhood. It is a way of communication during the period of developing autonomy and separation from caregivers, and is usually present in children between 1 year and 3 years of age who do not have enough vocabulary to express their feelings. Tantrums gradually decrease by 4–5 years, after which they are uncommon, and need intervention. Being tired, hungry, or sick, can make tantrums worse or more frequent.

Underlying neurological disorders like autism spectrum disorder and intellectual disability also make the child more prone for the persistence of temper tantrums. Underlying precipitants may include frustration, attention-seeking behavior, or unfulfilled demands. Parental factors like excessive disciplining, inconsistent parental attitudes and failure to set limits may also be responsible. Temper tantrums which last for more than 15 min, or occur regularly, or more than thrice-a-day, usually reflect some serious underlying medical, social or emotional problem.

## Management

Detailed history and examination is mandatory to find out if these problems are associated with hunger, fatigue and overstimulation. Exposure to abuse or stress at home may be the reason of persistence of this behavior, which otherwise would have subsided. Thorough physical examination to exclude physical abuse along with neurological and behavioral assessment is important.

Laboratory investigations include screening for iron-deficiency anemia and exposure to lead. Other investigations should be done if there are any clues found on examination.

If the child engages in undesired behavior, parent can ignore the undesired behavior. Undesired behavior is often being reinforced because it results in parental attention. Ignoring the undesired behavior reduces the frequency of that behavior over a period of time, as undesired behavior is no longer reinforced by parental attention. This process is called extinction. It is important to inform parents that with this process, the problem may worsen initially before it improves.

Punishment usually used is verbal reprimand or privilege withdrawal. One of the commonly used punishment strategies for children is time out. It is usually implemented by having a child sit in a chair, stand in the corner or go to the room for brief period usually 1–5 min. Time out facing a corner means that the child has limited access to those around her. Corporal punishment should not be used, though some behavioral techniques may be helpful (Box 1).

### BOX 1 Behavioral techniques that may help to prevent temper tantrums

- Be consistent
- Plan ahead
- Encourage your child to use words
- Let your child make choices
- Praise good behavior
- Distraction from the topic.

### IN A NUTSHELL

1. Behavioral problems are important for the pediatricians as they are common and majority of these patients are likely to present to a pediatrician first, rather than any specialist.
2. Common behavioral problems discussed in this chapter include infantile colic, thumb sucking, pica, rumination and temper tantrums.
3. In many other children attending for other acute or chronic medical conditions, these problems may be present but are not disclosed by parents due to their apparent unimportance or nonseriousness.
4. An integrated behavioral assessment should be routinely done by the pediatrician, so that these problems can be identified and underlying psychological factors addressed or other appropriate advice provided to parents.
5. In occasional patients, referral to mental health professionals may be needed if meeting the criteria for a mental or psychiatric disorder.

## Chapter 21.4

# Enuresis and Encopresis

Piyush Gupta, Ruchi Mishra

Micturition is an intricate function resulting from a coordinated activity of the muscles of the urinary bladder involving integration of both volitional and autonomic system. In infants, it is primarily under autonomic control and as the child develops this act becomes volitional. It is uninhibited for the first 16 months of life and as the child grows he becomes aware of the sense of bladder fullness and urinary frequency decreases. By 3 years, diurnal control is established and by 4 years most children develop nocturnal control also. Bowel control precedes bladder control in the sequence shown in **Flow chart 1**. Note that proper toilet training is essential for achieving continence.

**Flow chart 1** Sequence of bowel and bladder control

## ENURESIS (BEDWETTING)

Voluntary or involuntary repeated discharge of urine into clothes or bed, after a developmental age when bladder control should be established (usually 5 years), is labeled as enuresis. Bedwetting or urinary incontinence is labeled as enuresis only if urine is being voided twice a week for at least 3 consecutive months, or if it is causing clinically significant distress in the child's life. *Nocturnal enuresis* refers to voiding during sleep, whereas *diurnal enuresis* refers to daytime urination; these may or may not exist together. Approximately 10% of the children with nocturnal enuresis will have diurnal enuresis whereas 50% of children with diurnal enuresis have nocturnal enuresis. Approximately 10% of the 5-year-old, 5% of the 10-year-old and 1% of the 18-year-old children will have nocturnal enuresis.

## Classification

Enuresis may be primary or secondary. *Primary enuresis* is defined as repeated (at least twice a week for at least 3 consecutive months) passage of urine into clothes/bed during night in a child of age more than 5 years, who has never been dry in night. This is three times more common in boys. In *secondary or late-onset enuresis*, the child has been dry for at least 6 months before bedwetting begins again during sleep. In most of these children an underlying organic pathology is detected whereas primary enuresis is mostly idiopathic or behavioral in origin.

*Monosymptomatic (uncomplicated) nocturnal enuresis* involves voiding in the bed at night in the absence of other genitourinary or gastrointestinal symptoms, or daytime symptoms. It accounts for 80–85% of cases of nocturnal enuresis. Another 5–10% of the cases have associated daytime symptoms, such as urgency, frequency, urge incontinence, constipation, or encopresis. These children are labeled as having *polysymptomatic (complicated) nocturnal enuresis*.

## Etiopathogenesis

*Primary enuresis*, though multifactorial, could be related to sleep disorder. There is poor arousability in response to acoustic stimuli. Children are not able to appreciate when the bladder is full during sleep. Small functional bladder capacity and detrusor overactivity may play an important role in pathophysiology of nocturnal enuresis. It is often associated with frequent daytime voiding. Genetic factors include a positive family history in most cases. The risk of a child being affected is 43% if one parent had nocturnal enuresis and 77% if both parents were affected. Approximately 75% of children with nocturnal enuresis have a first-degree relative who had enuresis. Psychological causes may be related to stressors at home or school.

There might be a delay in neurological maturation to control bladder sphincter which is more pronounced in children with mental retardation or spinal cord abnormalities. This is substantiated by the fact that approximately 5% enuretics resolve their symptoms each year without intervention and only about 5% of 10-year-old and 1% of the adolescents remain enuretic.

The following factors have also been implicated in the pathology of nocturnal enuresis: hyposecretion of arginine vasopressin (AVP), decreased responsiveness to low urine osmolality, loss of circadian rhythm of antidiuretic hormone (ADH) secretion. Altered AVP receptor function in the tubule, diminished capacity to be aroused and altered sleep architecture. Less than 3% cases have organic etiology such as obstructive uropathy or urinary tract infections.

Children who undergo training late (after 24 months) are prone to develop late nocturnal bladder control; recommended age to begin toilet training is around 24 months, an age at which most developmentally normal children will be ready to be toilet-trained (**Box 1**). In general, *physiological* readiness for toilet-training occurs at around 18 months of age (can delay defecation or urination sufficiently to get to an appropriate place). However, *cognitive* maturity (to use the potty, to remember to use it, and to resist distraction long enough to complete the process) is usually achieved around 24 months. The *motor skills* needed to get to the bathroom, manage clothes, and sit still on the potty are also important, though parents may assist in some of these.

*Secondary enuresis* Too enthusiastic and immature toilet training can result in secondary enuresis. Other causes include emotional stress, parent child maladjustment, urinary tract infections, diabetes mellitus, or diabetes insipidus. Secondary enuresis is frequently associated with stressful or traumatic events at home or at school or anything related to the daily life of the child.

*Diurnal enuresis* This is more common in preschool girls, is usually due to micturition deferral (waiting till the last moment to pass urine and then being unable to hold any longer), and usually settles by age

### BOX 1 Readiness criteria (when to start toilet training) for a developmentally normal child

- Child stays dry at least 2 hours at a time during the day or is dry after naps
- Bowel movements are regular and predictable
- Facial expressions/posture/words show that your child is about to urinate/defecate
- Child can follow simple instructions and imitates parental behavior
- Child can walk to and from the bathroom and help undress
- Child seems uncomfortable with soiled diapers and wants a clean diaper
- Child asks to use the toilet or potty chair
- Can put on/take off clothes
- Follows parent into bathroom and expresses interest in the toilet.

Source: From AAP Website, from <http://www.pediatrics.org/cgi/content/full/109/3/e48>, and from Am Fam Physician. 2008;78:1059-64.

of 9 years. It is mostly caused by the impaired transition from reflex micturition control of infants to volitionally controlled micturition reflex in adults. Stress incontinence, urinary tract infection, bladder outlet obstruction, ectopic ureter and diabetes are the other causes of diurnal enuresis. Vaginal reflux of urine that seeps out upon rising is common physiological cause in young girls. Psychological causes include constant anxiety, loss of a parent, parental discord and abusive home environment. Some children fail to appreciate the sense of bladder fullness or ignore it while playing. When both diurnal enuresis and nocturnal enuresis are present, abnormalities of the urinary tract or voiding disorders are likely.

Chronic constipation is an important isolated risk factor for enuresis.

## Evaluation

History and examination should be able to rule out the possibility of any underlying neurological disorder, voiding dysfunction, polyuric conditions (diabetes mellitus, diabetes insipidus, chronic renal failure) and bacterial cystitis. Questions should be asked regarding daytime incontinence, urgency, frequency, posturing, infrequent voiding and frequent voiding. Details of sleep pattern, fluid consumption and bowel habits should also be obtained. A *frequency void chart* often helps to differentiate primary nocturnal enuresis from voiding dysfunction. Ideally an input-output chart should be maintained. The normal frequency of daytime void in a child is 4–7 times per day. A frequency of more than eight times or at duration of less than 2 hours is considered abnormal. Look for any deformity of spine or foot; or abnormality of gait. Physical signs of occult spinal deformities such as dimples, tuft of hair, skin discoloration, lipoma and asymmetrical buttocks may be useful. Anal sphincter tone and perineal sensation and reflexes should be assessed. Genital examination is a must for all children. In boys abnormal meatus or abnormal urinary stream should be evaluated. In girls, look for labial adhesions and ectopic ureteral openings.

Investigations for primary nocturnal enuresis involve routine urine examination including osmolality, microscopy, reducing substance and culture. A good *ultrasonogram* (USG) on full bladder can also give a rough estimate of bladder capacity. Postvoid residual urine volume should be assessed during USG to guide regarding presence of voiding-dysfunction. *Urodynamic study* is needed to assess bladder capacity and detrusor pressures in a child who has an abnormal frequency void chart.

## Management

The timing of initiation of treatment for monosymptomatic nocturnal enuresis varies from child to child. The major determinants are whether the child and caregivers view the enuresis as a problem and how strongly motivated they are to participate in a treatment program. Any serious attempts to treat the condition should begin only beyond 7–8 years of age as enuresis interferes with socialization and behavior in older children. Management goal should be aimed at completely stopping the enuresis. After establishing the diagnosis of primary nocturnal enuresis a treatment plan should be discussed with the parent. Cooperation of the child in the management plan is essential.

### Nonpharmacological Measures

These are effective in 30% cases and consist of behavior modification, alarm systems and bladder strengthening exercises.

*Behavioral treatment* is the first mode of therapy for a child with enuresis without any disorder of the genitourinary tract.

- Counseling and reassurance to the family is the most essential step. They need to be assured of the benign nature of the condition and high spontaneous resolution rate.

- Ask the parents to maintain a diary record of dry nights; reward the child for such nights.
- Parents should provide emotional support to the child, not to criticize and changing the bedsheets without child's notice.
- Avoid punitive measures. Positive reinforcement has been shown to have a success rate of more than 85%. Parents should understand that enuresis is not under volitional control so punishment is counterproductive.
- Children should have an early dinner and appropriate fluids with dinner. It is recommended to avoid any form of fluid at least 2–3 hours prior to sleep. Ask the child to void before going to sleep. Ample consumption of fluid in the morning and afternoon reduces the need for significant intake later in the day. Isolated night-time fluid restriction, without compensatory increase in daytime fluid consumption, may prevent the child from meeting his or her daily fluid requirement and is usually unsuccessful.
- Encourage regular daytime voiding schedule, emptying the bladder before going to sleep and getting adequate sleep should also be encouraged.
- Clinicians should also be aware of any comorbid condition like constipation, encopresis, and any psychiatric disturbance. Treating the comorbidity often rectifies the incontinence.
- Repeated waking to void is not helpful, though using an alarm clock to wake the child once, 2–3 hours after falling asleep is indicated. Child should be fully aroused and walk unaided to the toilet to urinate. Advantage of an alarm is that the child becomes aware of a sense of bladder fullness during sleep also.

*Behavior conditioning or alarm system* Behavior conditioning with use of alarms is extremely effective. Enuresis alarms are a first-line treatment for children whose bedwetting has not responded to advice about fluid intake, toileting, or an appropriate reward system. Enuresis alarms work best for well-motivated families and children with frequent enuresis (more than twice per week). The alarm is either a sound or a vibratory device that may be clipped to the underwear or kept at the bedside and rings as soon as voiding starts. The child must get out of bed and finish the act of urination or must hold the act until later. It is the most helpful way in training the child to improve bladder capacity and avoid enuresis. It requires long-term use and approximately 70% improve with 5–12 weeks of this therapy. Relapse rates are lower (15–30% in 6 months after treatment) than that with pharmacotherapy.

*Bladder training exercises* Daytime bladder exercises are useful, especially in those with low functional bladder capacity. The following bladder exercises have been found to be helpful; (1) hold urine as long as possible during the day to increase the functional bladder capacity; (2) practice repeated starting and stopping the stream at the toilet bowl; (3) practice getting up from bed and going to the bathroom at bedtime before sleep. Kegel's exercise, i.e., volitional contraction of pelvic floor muscles increases the detrusor contractions.

*Caffeine reduction* Some soft drinks, cocoa and chocolates have significant amount of caffeine which is known to have a diuretic action. Excessive consumption of these items can result in enuresis and should be avoided.

### Pharmacological Measures

Medications are indicated only in children older than 6 years who fail behavioral treatment. Drugs used are (1) imipramine; (2) desmopressin (DDAVP); and (3) oxybutynin.

- *Tablet imipramine (25 mg and 50 mg tablets)* 6–8 years (25 mg), 9–12 years (50 mg), greater than 12 years (75 mg) once a day at bedtime. It is a tricyclic antidepressant which alters the arousal-sleep mechanism. It combines the anticholinergic

effect to increase the bladder capacity with a noradrenergic effect to decrease detrusor contractions. Success rate is 30–60%, whereas relapse rate may be up to 90%. The relapse rate can be decreased if treated for 3–4 months followed by tapering over 3–4 weeks. Common side effects are drowsiness, lethargy, sleep disturbances and cardiotoxic side effects.

- Desmopressin acetate (DDAVP) orally or intranasally (nasal spray, 10 µg per spray) at bedtime. It acts by reducing the nocturnal urine output to a volume less than the functional bladder capacity. Start with 10 µg given at bedtime daily and increase gradually by 10 µg/week to a maximum of 40 µg/day. If effective, it should be used for 3–6 months. Success rate is 40–60%, whereas relapse rate may be up to 90%. It is a costly drug, and has a fast onset of action. It may be used intermittently to allow enuretic children to participate in sleepovers and night camps.
- Oxybutynin is an anticholinergic agent that can be used in those above 6 years of age. It reduces uninhibited bladder contractions and is useful in children manifesting with urgency and urge incontinence during daytime.

Management is summarized in **Box 2**. The various treatment modalities available are not used exclusive of each other and often a combination works best. Failure of one form of therapy should result in substitution or addition of another. The best treatment option, if behavioral therapy fails, is the use of combination therapy with alarms and drugs simultaneously. Evidence is not robust to support the use of hypnosis, psychotherapy, acupuncture, chiropractic, and medicinal herbs for treatment of nocturnal enuresis.

#### BOX 2 Management of enuresis

- Goal of treatment is complete stopping of enuresis
- Initiate treatment after 7–8 years of life
- Coordination between clinician, parent and child required.

##### Nonpharmacological measures

- *Behavior modification*: Includes reassurance and counseling of both parents and child including dietary modification
- *Alarm therapy*: Works best for motivated children and families. Helpful in children with frequent symptoms
- *Bladder exercises*: Useful especially in those with low functional bladder capacity.

##### Pharmacological measures

- *Imipramine*: Combines the anticholinergic effect to increase the bladder capacity with a noradrenergic effect to decrease detrusor contractions
- *Desmopressin*: Acts by reducing the nocturnal urine output to a volume less than the functional bladder capacity
- *Oxybutynin*: Reduces uninhibited bladder contractions and useful in children manifesting with urgency and urge incontinence during the daytime.

**Combination of various treatment modalities often works best.**

Nonresponse to active intervention is defined by less than 50% improvement in symptoms. When motivated children and families do not respond to an adequate trial of treatment with an enuresis alarm (i.e., 3 months) and/or desmopressin (at a dose of 0.4 mg), referral to a health-care professional who specializes in the management of bedwetting that has not responded to initial treatment (e.g., developmental-behavioral pediatrician, pediatric nephrologist or urologist) may be warranted.

## ENCOPRESIS

Defecation is the process of consciously emptying the bowel and continence is the ability to control this act. Fecal continence is regulated by a coordinated action involving the neuromuscular reflex on the anus, rectum, the two anal sphincters and the levator

ani muscles. Conscious bowel control is attained at the age of 28 months on an average. Fecal incontinence is categorized as true incontinence, partial incontinence and overflow incontinence. Impaired neuromuscular function or deficient anorectal muscles as in imperforate anus result in true incontinence. Insufficient anorectal pressure or impaired sensation of peristaltic movement and bowel distension prevents complete evacuation of the bowel resulting in continuing passage of small amounts of feces. Overflow incontinence, results from chronic fecal impaction and leakage of liquid feces through the dilated anorectal ring.

### Definition

*Encopresis* is defined as the involuntary or voluntary passage of formed feces, at inappropriate places (usually into the underwear) in the absence of any physical pathology, after 4 years of age. The act should occur at least once every month for 3 consecutive months. Encopresis is more common in boys with the peak age of affliction being 5–6 years.

### Classification

Encopresis can be *primary* (children who were never continent since infancy) or *secondary* (children with a typical history of clean periods, followed by a relapse of symptoms). Encopresis is also classified as *retentive* and *nonretentive* based on retention of feces for a prolonged time. Approximately two-thirds cases are retentive type and associated with chronic constipation. Nonretentive encopresis is a behavioral or psychological problem.

### Pathophysiology

The course of the rectum is aligned at an approximate angle of 90° to the anal canal. This sharp bend favors rectal continence. The contraction of levator ani muscle which causes the straightening of the anorectal canal results in defecation. The sympathetic nervous system causes rectal filling by relaxing the sigmoid and rectum and contracting the internal anal sphincter. The parasympathetic fibers control bowel emptying by reversing the above. Incontinence occurs when the pressure induced by the peristaltic movement in the distal rectum overcomes the anorectal pressure.

### Etiology

The etiology of encopresis is multifactorial and includes—psychological, anatomical, genetic, physiological and dietary elements. Abnormal gastrointestinal motility and developmental delay also play a part. In most cases, encopresis is thought to develop as a consequence of chronic constipation with resulting overflow incontinence (retentive encopresis). Psychological factors are especially important for secondary incontinence. In many cases encopresis occurs when there is a stressful family situation, such as divorce, birth of a sibling, or a transition such as starting school. When a child actually smears feces, there is a strong indication that there may be a problem in family relationships. The child who is reluctant to openly express anger may express it by soiling. Soiling may also occur in a child who has had a traumatic or frightening experience, such as sexual or physical molestation. Coercive toilet training can also result in encopresis. Other problems to be considered in the diagnosis include the following (especially in cases of primary incontinence): spina bifida, meningomyelocele, spinal-cord injury with dysfunction of the anal sphincter, tethered spinal cord, ultrashort-segment Hirschsprung disease and imperforate anus with fistula.

### Clinical Features

The first and foremost consideration is given to constipation which is often a result of overzealous toilet training by parents, resulting in reactionary fecal retention (often out of anger or retaliation).

Children with nonretentive incontinence are often the products of disturbed homes and with a poor parent-child relationship so that a regular pattern of toilet training was never achieved. Approximately 80–95% of children with encopresis have a history of constipation or painful bowel movements. The remaining 5–20% appears to have nonretentive encopresis and no history of constipation or painful defecation; they generally have no evidence of incomplete evacuation on physical evaluation or radiographic evaluation.

Secondary encopresis is often a result of stress at home or at school and whereas primary is associated with developmental delay and enuresis. This picture is further complicated by behavior and psychological abnormalities in such children. Punitive measures by parents always do more harm than good. Encopresis has adverse implication on school performance and attendance as child is often looked down upon his peers for the foul smell emanating from him.

## Diagnosis

**History** The main aim of the history should be to differentiate between retentive and nonretentive incontinence. It is important to determine whether it is primary or secondary encopresis. The age of onset of incontinence, also frequency of symptoms, stool mass and consistency, any alteration in bowel habits, the time of day it happens and any other related behavioral issues should be noted. Parent-child relation, marital discord or any other family issue should be looked up. Enquiry should be made if the child has sense of fullness, the urge to defecate and the ability to differentiate between the passage of feces and flatus. Urinary abnormality and lower limb weakness should also be assessed when suspecting spinal cord involvement. Details about toilet training should also be elicited as coercive toilet training can lead to fecal retention late. The skin over the spine should be examined for any midline defects. Sphincter tone should be assessed.

**Clinical and laboratory tests** These are undertaken for primary incontinence when anatomical abnormality or neuromuscular dysfunction is suspected. These include proctoscopy and fiberoptic studies of the lower bowel to rule out any structural abnormality. Barium enema and defecography study may be required to monitor the act of defecation in cases where anatomical abnormality is suspected. Specific studies may sometimes include anal sphincter electromyography (in children with suspicion of anal sphincter abnormality), manometric studies, CT of puborectal muscles and external sphincter (for associated anomalies). Sacral ratio (dividing the distance from the lowest point of the sacrum to the line joining the two posterior iliac spines by the distance from that latter line to the line joining the upper limits of the iliac crest) less than 0.52 correlate well with spinal cord anomalies and unfavorable prognosis in children with anorectal malformation.

## Management

The approach to treating a child mainly aims at establishing the normal bowel habit and improving the child to parent relationship. It includes both pharmacological and nonpharmacological measures. There are three main areas of intervention: (1) immediate relief from constipation; (2) long-term relief from constipation through diet and drugs and (3) behavioral therapy and biofeedback training.

Immediate relief of fecal retention in children is achieved by a glycerin suppository or sodium phosphate enema (6 mL/kg). For a slower relief of symptoms over 5–7 days, the available options include oral administration of polyethylene glycol (1.5 g/kg/day × 3

days), lactulose (2–3 mL/kg/day q 12 hours × 7 days), or mineral oil (3 mL/kg/day q 12 hours × 7 days). The dose should be sufficient to produce 1–2 soft stools daily. Long-term laxative use is to be avoided. After removal of impacted stool, plan long-term management of constipation, primarily through dietary modification. A few children may also require long-term maintenance therapy for relief of constipation. Dietary changes are an important management element. Dietary counseling of both parent and child is required to promote the inclusion of fiber in diet. Excessive flatus and soiling may be avoided by preventing certain food types. Dietary recommendations for few children with retentive encopresis are summarized in **Box 3**. In few cases tricyclic antidepressants have been tried but they should be used with caution in young children because of their narrow therapeutic index and potential risk of arrhythmia. They should be avoided in children with retentive incontinence as they may exacerbate constipation.

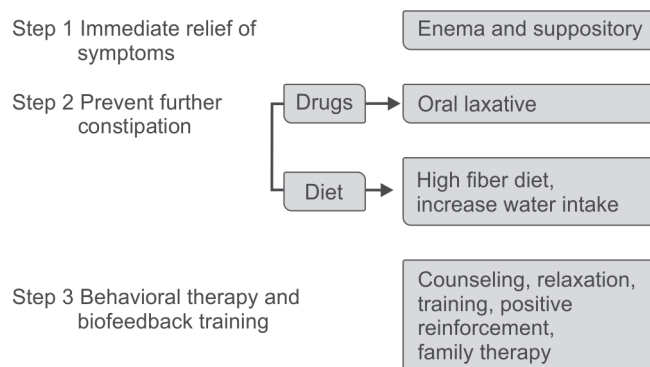

### BOX 3 Dietary recommendations for retentive encopresis

- Reduce the intake of dairy products and bananas (constipating foods)
- Increase intake of high-fiber foods such as bran, whole wheat products, fruit and vegetables
- Increase intake of water and other liquids. Avoid sweetened and high calorie drinks
- Limit drinks with caffeine, such as cola drinks and tea
- Eat well-balanced meals and snacks, and limit fast foods/junk foods that are high in fats and sugars
- Limit whole milk to about 250–300 mL a day for child over 2 years of age.

Concomitant behavioral management is required which lays stress on regular postprandial toilet (sitting on potty seat for 10–15 min after the meal) and adoption of high-fiber diet. Often it may be months before regular bowel habits are acquired. Punitive measures are a strict number. Parents need counseling to be supportive and patient with the child. Compliance may wane with time so reinforcement of behavior therapy along with continued use of high-fiber diet is indicated. Biofeedback training, behavior modification and muscle training coupled with appropriate medication is mostly beneficial. Failure of medical management occasionally requires surgical correction. Long-term studies indicate that encopresis improves irrespective of the method used. **Flow chart 2** summarizes the key strategies in management of encopresis.

Individuals with impaired bowel and bladder control often have low self-esteem with lower perceived quality of life on several domains so an integrated approach involving both the parent and the child along with the treating physician has the most promising outcome.

**Flow chart 2** Management of encopresis

### IN A NUTSHELL

1. Age-appropriate and proper toilet training is essential for preventing incontinence.
2. Overenthusiastic toilet training is as detrimental as incomplete training.
3. A good history and examination of the child are cornerstones for diagnosis.
4. Behavior therapy and dietary modifications often obviate the use of pharmacological measures.
5. Punitive measures do more harm than good whereas parental support can change the outcome in a positive way.

## Chapter 21.5

# Breath-Holding Spells

Sumaira Khalil, Devendra Mishra

Breath-holding spells (BHS) are paroxysmal nonepileptic disorders seen commonly in children belonging to the age group of 6–28 months old, though they may occur even in the first few days of life and up to 6 years. The spells can be either cyanotic or pallid, and the episode frequency may vary from several episodes in a day to as rarely as one or two episodes in a year. First described almost 3 centuries back, BHS are an important differential diagnosis of epileptic seizures among preschoolers. Given that the diagnosis is entirely clinical, with investigations infrequently providing additional diagnostic information, it is not uncommon in practice to find children with BHS being treated with antiepileptic drugs.

### Epidemiology

They constitute 4–18% of all the psychosomatic disorders seen in the pediatric age group. Among otherwise normal children, up to 27% may have BHS with a male to female ratio of 3:1. However, a community survey in India among 0–3-year-old children reported BHS to be the most common psychiatric disorder in this age-group but with a prevalence of only 5.9%. There was no difference in prevalence among rural, urban and slum children. Among an Indian general hospital psychiatry clinic, 11% of the preschoolers had BHS.

### Etiology

A positive family history is present in 23–38% of children with spells suggesting some genetic association. An analysis of family members of children with breath-holding spells showed a 50:50 risk of inheritance from an affected parent. The inheritance pattern based on a regression model for pedigree analysis has suggested autosomal dominant pattern with reduced penetrance. Several times presence of both types of spells is seen in the same family, thereby hinting at a close relationship between cyanotic breath-holding spells and pallid breath-holding spells.

Along-held belief has been voluntary breath-holding as a cause of BHS. However, cinefluoroscopy has shown conclusively that these episodes occur during expiration, and are thus involuntary. Another factor considered to have important etiopathological role has been the presence of behavioral problems in BHS. Children with BHS were described as “neuropathic children of neuropathic parents” almost a century back. Some workers suggested correlation between behavioral problems and BHS, including abnormal behavior like temper tantrums and hyperactivity in 30% of these children. Di Mario et al. reported no significant difference in behavior of children with BHS as compared to their controls suggesting that BHS are nonvolitional and cannot be synonymous to temperamentally difficult children. Another study among Indian children with BHS also reported no apparent difference in parental attitudes or in children’s habits.

A correlation between BHS and syncopal episodes later in life has been shown. Up to 17% children with BHS are reported to develop neurogenic syncope later in childhood or adolescence. The proposed mechanism is the underlying vagal stimulation as a cause for both pallid BHS and neurogenic syncopal episodes.

Some workers have suggested a maturational delay in myelination of brainstem to have a role in the etiology of breath-holding spells in children, whereas others have reported altered

selenium and antioxidant levels in children with BHS. However, the pathophysiologic or therapeutic significance of these findings still remains to be elucidated.

### Pathogenesis

The pathogenesis of BHS is quite unclear and controversial. Both types of spells result from reflex changes that reduce cerebral blood flow, though the exact mechanism may vary from one child to another. Intrapulmonary shunting, disorder of ventilator chemosensitivity and autonomic dysregulation are some of the theories related to the pathophysiology of cyanotic BHS. The loss of consciousness in a BHS is attributed to drop in blood pressure due to increased intrathoracic pressure because of breath holding during expiration. This further causes a greater than normal drop in cerebral blood pressure and due to simultaneous drop in the cerebral vascular resistance the cerebral blood flow is further reduced leading to cerebral hypoxia causing unconsciousness and seizures. Dysregulation of the autonomic nervous system is known to cause vagal mediated cardiac arrest and anoxia.

A relationship between BHS and cardiorespiratory control has also been proposed. Airway obstruction during BHS is mediated by autonomic dysregulation which also controls the patency of the airways. Children with cyanotic BHS have been shown to have a greater increase in pulse rate and greater decrease in diastolic blood pressure without an increase in systolic blood pressure after standing from the supine position. These results support the hypothesis that children with cyanotic BHS have underlying autonomic nervous system dysregulation. The ECG changes before and during BHS spell have also been studied. Sinus arrhythmia and asystole were seen more during pallid breath-holding spells. Moreover, children with iron-deficiency had a lower frequency of respiratory sinus arrhythmia and prolonged asystole time during the spell. This study, thus, demonstrated both the presence of autonomic dysregulation in children with BHS and the effect of iron deficiency on it.

Pallid spells are proposed to be due to parasympathetic system mediated cardiac inhibition leading to bradycardia. The primary mechanism is due to increased vagal tone leading to cerebral hypoperfusion.

Anemia is believed to have a strong association with the disorder. Regardless of the type of the spells, iron-deficiency anemia is known to prolong the duration of asystole during the spell. Low levels of hemoglobin results in decreased oxygen carrying capacity and prolonged cerebral anoxia in an already irritable child secondary to iron-deficiency, which increases the occurrence of a BHS. Complete resolution of spells has been shown in 50% patients on iron therapy, and 50% reduction in another 36.4% of children. Others have suggested a possible relationship between maternal iron-deficiency anemia and children with BHS. The role of iron in BHS is possibly related to it being a cofactor in catecholamine metabolism and neurotransmitter function.

### Clinical Features

Breath-holding spells are commonly seen in developmentally normal children occurring numerous times a day to one episode a year. They start at around 6–18 months of age and usually disappear by 5–6 years of age. By 4 years almost 50% children will be free of spells, and almost all by 7–8 years. BHS typically occur in four phases: (1) provocation, (2) apnea and cyanosis (3) opisthotonic rigidity or abnormal posturing and (4) stupor (**Box 1**). They are classified by the color change of the child during an attack as cyanotic and pallid BHS. In 20% of children, both types of breath holding could be present and are called as mixed episodes. Usually

BHS do not result in serious complications but rare case reports of cause status epilepticus or asystole exist, mostly in those with a complicated medical history, or with severe spells.

#### BOX 1 Characteristic features of breath-holding spells

- Episodes start between the ages of 6 months and 18 months
- Attack frequency varies from many per day to only a few at irregular intervals and may increase during the 2nd year of life
- Characteristic sequence consists of a provocative stimulus, apnea and color-change, limpness, followed by opisthotonic rigidity
- The child regains consciousness within few minutes
- Child may sleep for several hours, especially following a pallid episode
- Family history of breath-holding spells is present in around 30% patients
- The physical examination is normal.

*Cyanotic breath-holding spells* are the most common type, seen in 54–62% of children with BHS. They usually occur in response to anger, leading to a vigorous cry, followed by apnea and rapid onset of cyanosis. This may or may not be followed by loss of consciousness, associated with bradycardia, abnormal posturing or repeated generalized clonic jerks. After regaining consciousness, which is usually within a minute, the child is usually awake and resumes normal activities.

*Pallid breath-holding spells* are seen in about 19–24% of children. They are similar to vasovagal attacks where the child turns pale and can be induced by ocular compression. Pallid spells usually occur in response to fright and pain, or an unexpected event. The child may gasp or cry, stops breathing, becomes hypotonic and loses consciousness; clonic movements may occasionally occur. Sometimes they are associated with prolonged period of asystole and bradycardia. Importantly, after attaining consciousness, pallid spells may occasionally be followed by sleep for several hours.

### Diagnosis

The diagnosis of BHS depends only on a good and detailed clinical history, describing the entire episode as and when it occurred. It should also include presence of any precipitating event like emotional stimuli or trauma. Other important clues from the history that could help in diagnosis include the presence or urinary incontinence, uprolling of eyeballs, and deviation of mouth, which are more commonly seen with seizures, especially if not preceded by a cry. If feasible, parents may be encouraged to make a video recording of a typical episode that could further help in confirming the diagnosis.

A complete physical examination including growth and development is essential, especially cardiovascular examination for any rhythm disturbances or murmurs. No imaging or specific laboratory test is needed to make the diagnosis. An electroencephalogram (EEG) is usually not indicated unless the history is incomplete or unclear, convulsive activity is too prolonged or seizure cannot be ruled out on the basis of history.

An important differential of pallid BHS is long-QT syndrome, a congenital condition characterized by loss of consciousness precipitated by injury, fright or excitement. Thus, an electrocardiogram is an essential investigation in all children with pallid BHS. Hypercyanotic spells in children with cyanotic congenital heart disease are a close differential for cyanotic BHS. In addition to absence of baseline cyanosis, clubbing, and cardiovascular findings in BHS, the time to appearance of cyanosis during the episode also helps in differentiating it from cyanotic heart disease. During a hypercyanotic spell in a child with right to left shunt, there is a baseline cyanosis which increases during the episode even while the child is crying; whereas during a BHS, the cyanosis appears when the child has stopped crying/breathing.

Ocular compression during cardiovascular monitoring or EEG recording has been shown to demonstrate abnormalities (asystole or slowing/voltage attenuation, respectively) in children with pallid BHS. But the clinical utility and safety of this maneuver is controversial and it is best avoided outside of a specialized center.

### Management

Reassurance to the parents regarding the benign nature of BHS is the mainstay of treatment (**Box 2**). The parents must be informed about the low risk of epilepsy and developmental delay in such children. During a spell, the child must be placed in the lateral recumbent position rather than upright on the shoulder, as it shortens the period of cerebral anoxia. Behavioral modification also needs to be directed at reducing the parents' emotional reactions to the episodes.

#### BOX 2 Information to be conveyed to parents of a child with breath-holding spells

- Benign and self-limiting episodes
- During the episode, place the child in lateral/recovery position, away from harm
- Inappropriate attempts for vigorous resuscitation may do more harm than benefit
- Attack frequency may increase during the 2nd year of life
- No increase in risk for developmental delay or epilepsy
- No extra attention to the child with BHS, compared to siblings
- Report back in event of prolonged episodes, life-threatening episodes, very frequent spells, or change in pattern of episodes.

Iron therapy, which has been shown to be beneficial, must be initiated in all children with BHS, with or without iron-deficiency anemia. According to the Cochrane review published in 2010, iron supplementation (at 5 mg/kg/day of elemental iron for 16 weeks) appears to reduce the frequency and severity of the spells, and is of particular benefit in children with iron-deficiency anemia where response correlates with improvement in hemoglobin. This benefits children more who have associated iron-deficiency anemia with data showing a trend towards greater improvement in spells linked to improvements in hemoglobin level. There is paucity of data to prove the role of iron in children who are not anemic or have normal hemoglobin levels. Given the high prevalence of iron-deficiency in children in our country, we feel that the optimum approach would be to provide therapeutic doses to those with iron-deficiency (3–6 mg/kg/day for 4 months) and daily maintenance requirement (2 mg/kg/day) to those without iron-deficiency. The duration can be further tailored on the basis of response.

Atropine has been shown to be effective in pallid BHS (0.01 mg/kg 2–3 times a day) but is rarely required. Piracetam (40 mg/kg/day), although not approved for this indication, is proven to be safe and effective in children with severe and multiple BHS. As the convulsive movements associated with BHS are not epileptic, presently there is no role of anticonvulsants in the management of BHS. Permanent cardiac pacemaker implantation has been tried with success in rare cases of severe BHS not responding to medical management, or those with prolonged asystole following the spells. Other drugs that have been studied in treatment of BHS are glycopyrrolate, theophylline, fluoxetine, and levetiracetam but need further data to confirm their efficacy and safety.

Breath-holding spells are common in preschool children and have excellent prognosis and the crux of diagnosis is a detailed history from an eyewitness. Importance of the condition for the physician is the frequent misdiagnosis of epilepsy and the urge to investigate extensively. For the parents, the correct diagnosis reassures about the benign nature of this apparent life-threatening event and favorable long-term prognosis.

### IN A NUTSHELL

1. Breath-holding spells are common childhood events and are an important differential for childhood seizures.
2. A good history from an eye-witness, especially focusing on the events before the episode, is crucial for an accurate diagnosis.
3. Investigations like EEG or neuroimaging, and treatment with anticonvulsants are not helpful and routine use should be avoided.
4. Iron-deficiency, overt or subclinical, is common and iron therapy is beneficial in reducing the frequency and severity of the episodes.
5. Long-term prognosis for breath-holding spells is good.

## Chapter 21.6

# Common Speech, Language and Communication Disorders

Prathibha Karanth

It is important to be aware of three important aspects of communication that is speech, language and communication. While *speech* refers to the heard speech that one learns to understand through hearing and produce orally, *language* is the more comprehensive system that governs the rules underlying our speech in both comprehension and production. Speech cannot be understood and produced without the rules of language. Spoken language is referred to as the primary mode of communication while reading and writing, which are mapped on to speech, are the secondary system of language. *Communication* on the other hand refers to all means of exchange of information between individuals including the nonverbal (gestures and signs), the visual (symbols and pictures) and technological (Morse code, telephone, Skype, typing, email, etc.). With the phenomenal increase in the variety of the modes of communication in modern society, their usage in the learning process and day-to-day communication and the fact that these can be selectively affected, speech and language disorders are now viewed/studied within the broader framework of communication disorders.

Proficiency across different modes of communication at different levels of complexity is acquired in different stages of life. However, the most crucial aspects of communication that is the basics of speech and language are learnt in early childhood. Delays and deficiencies in communication skills can affect the child's overall well being by interfering not only in communication, but also affecting the child's social, educational and emotional well being and have a lifelong impact. It is therefore crucial to identify common communication disorders early in childhood and provide the necessary intervention to ameliorate and/or prevent these long-term effects. Communication disorders are generally more common in boys than girls with a ratio of 4:1.

## INCIDENCE AND PREVALENCE

Precise information on incidence and prevalence figures for communication disorders are hard to come by given the range of communication disorders both in terms of types and the wide age range in which they occur. Most studies focus on any one subtype. Overall figures for prevalence of speech, language and communication disorders range from 2% to 25% of the population, with a general consensus centering around 10%. The variance is due to the specific communication disorders being investigated, definition of disorders, mode of identification, age and number of participants.

Reliable reports of incidence and prevalence studies of communication disorders in children in India are even harder to come by. The Indian Census (2011) defining speech disability as *persons who speak in single words and are not able to speak in sentences* arrived at prevalence figures of 683,702 individuals up to the age of 18 years. Given the very broad definition of *speech disability* it is likely that this is an underestimate and the prevalence is in fact considerably higher.

## PATHOGENESIS

The majority of the childhood communication disorders are now known to be caused by congenital/genetic factors. History of communication disorders in other members of the family such as parents and siblings is reported to be between 28% and 60%. The genetic basis of conditions such as a congenital hearing loss have been long known. The genetic links of hitherto poorly understood childhood communication disorders such as specific language impairment (SLI) and autism spectrum disorders (ASD) are now being unraveled, though the exact genetic basis/mechanisms are yet to be understood. A smaller proportion of communication disorders in children are secondary to other conditions such as birth complications and postnatal infections, and injuries, such as hypoxia, otitis media, meningitis and head injuries. An even smaller proportion could be due to environmental factors such as extreme social deprivation and lack of speech stimulation, highly multilingual context and/or constant changes in the linguistic environment due to frequent relocations of the family in early childhood.

## Range of Communication Disorders

Children with communication disorders may not speak at all or their communication skills are not on par with their peers, in any one or more aspect—vocabulary, grammar, clarity of speech, control over voice, smooth flow of speech, specific difficulties in reading, and/or writing and the proper use of language in social situations.

For a child to acquire communication skills it is important that the underlying mechanisms of human communication such as good hearing sensitivity, perception, structural integrity of the brain and body, intelligence, motor control over the voice and speech producing mechanisms and emotional stability should be present. In addition a stimulating environment, which provides adequate language exposure and reinforces the child's attempts at communication, commensurate with age and developmental stage, is also a prerequisite for the smooth development of communication skills.

## CLASSIFICATION

The description and classification of communication disorders in the early and mid part of the twentieth century, was initially influenced by causation, within the medical model. Hence, for instance there were classificatory labels of *mental retardation with speech delay* or *hearing impairment with speech delay* or *cleft palate with speech delay* and so on. However, with the impact of linguistics on the understanding and study of both child language acquisition and its disorders, in the latter part of the twentieth century the characterization and broader classification of speech disorders was extended to include the language disorders. Under the medical model of classifications, communication disorders in children are generally classified with reference to the medical cause that underlies or is comorbid with the disorder. For instance, speech disorders would be classified as *childhood apraxia of speech* or *dysarthria* or *orofacial myofunctional disorders*; language disorders would be *childhood aphasia* or *selective mutism*. In addition, there would be speech-language disorders associated with *autism* or *traumatic brain injury*. The reservation against this type of a classification has been that, while it specifies the cause it does not provide an accurate description of the nature of the communication difficulty per se that is needed for speech-language therapy.

Current classificatory systems used by audiologists and speech language pathologists (ASLPs) are therefore based on the broader framework of the aspect of communication that is impacted such as articulation disorders, voice disorders, fluency disorders and language disorders. Among these four the first three, i.e., impairments of the articulation of speech sounds, fluency and/or voice are considered as speech disorders. Communication disorders in children have also been classified on the basis of the aspect of communication that is affected. This system groups them into four basic subtypes as (1) Articulation disorders; (2) Voice disorders; (3) Fluency disorders and (4) Language disorders. It is to be noted that a given child may have a disorder in one or more of these aspects of communication.

### Articulation Disorders

Articulation disorders are those that affect the clarity of speech sound production. Articulation disorders can be caused by hearing impairment, neurologic problems such as verbal apraxia or dysarthria or structural defects of the articulators such as a tongue-tie, cleft lip or misaligned teeth. Speech sounds in these conditions lack clarity because of distortions, or the omissions and substitutions of 'difficult to produce' sounds. Articulation disorders are at times referred to as phonological disorders. However, the latter denote speech discrimination difficulties and/or speech production issues.

### Voice Disorders

Voice disorders refer to abnormal production of voice. The abnormality is characterized by the use of pitch, loudness, resonance or duration that are not appropriate for the child's age and sex. For example in *puberphonia* the typical changes in voice that occur, more noticeably in males at puberty, do not take place, leaving the young male with a high pitched voice that is inappropriate to his sex. Or the oro pharyngeal cavity in a child with an unrepaired cleft palate would result in distorted resonance with speech, acquiring a hyper nasal quality. Hoarseness of voice is also a common condition and if untreated could lead to lifelong voice disorders.

### Fluency Disorders

Fluency disorders are characterized by difficulties in the continuity, rhythm and smooth flow of speech with repetitions of syllables, words or phrases along with tension in the speech mechanisms. Commonly known as stammering or stuttering, fluency disorders tend to occur in 4–5% of children between the ages of 2 years and 4 years. As with the other communication disorders they are more common among boys than girls (3:1) and may co-occur with other speech disorders, especially in articulation.

### Language Disorders

Language disorders are delays or disorders in acquisition of language affecting one or more aspects of language including phonology, semantics, syntax, and pragmatics as well as higher order language skills such as discourse. Children with language disorders may exhibit impaired comprehension and/or use of any one or more of the communication modes such as the spoken, written, and/or other symbol systems such as gestures and signs. Children with language disorders have issues in any one or more aspects of communication such as the form, content, and/or function of language in communication.

Language acquisition is affected in all of the congenital developmental disabilities such as hearing impairment, cerebral palsy and mental retardation. They may also be the consequence of degenerative neurologic disorders, infection, head injury or

neglect. Moderate to severe language disorders in these children persist along with impairments in developmental skills such as motor and functional skills as well as cognitive and social development, in the preschool years. With estimated prevalence rates of 2–19% they tend to have long-term difficulties in schooling along with behavioral issues.

A major subcategory of language disorders in children, that has emerged in the last decade or two include the developmental language disorders with no clear understanding as yet of the underlying pathology. Specific language impairment (SLI) which is representative of this group, is diagnosed when children present with language maturation which is at least 12 months behind their chronological age, in the absence of sensory or intellectual defects, pervasive developmental disorders, evident cerebral damage, and adequate social and emotional conditions. SLI is considered one of the most common childhood disorders, affecting 7% of children. As with other children with language disorders there are often associated impairments in other developmental skills such as motor skills, but to a much milder and nonapparent degree. A genetic basis is strongly suspected given the higher incidence in families with a similar history. Many of these children are later found to have difficulties in learning to read.

Auditory processing issues in children whose peripheral hearing is essentially within normal limits is also being increasingly documented under the label of Auditory processing disorders (APD), earlier referred to as Central auditory processing disorders (CAPD). Whether APD and SLI are essentially two faces of the same coin remains debatable.

Apart from these established traditional categories of children with developmental disorders, SLPs are increasingly contributing to populations of children with developmental disorders which until recently were not seen as being communication disorders. For instance, it is only during the last couple of decades that it is acknowledged that children with learning disabilities (LD) often have subtle underlying or associated speech and language disorders, which went unrecognized until the advances in speech language assessment that took place in the latter half of the twentieth century. Similarly, the loss or abnormal use of language seen in children with Autism Spectrum Disorders (ASD) were seen as secondary to the core disability in ASD, but are now increasingly being seen as a part of the core disability with implications for the individual's psychological, sociological, and educational growth. The contribution of speech language therapy, for amelioration of these issues, is also now being documented.

### Learning Disabilities

Learning disabilities is defined by the US National Joint Committee on Learning Disabilities (LD) as a *general term to refer to a heterogeneous group of disorders manifested by significant difficulties in the acquisition and use of listening, speaking, reading, writing, reasoning, or mathematical skills*. Developmental language disorders such as SLI is now documented as being the most common developmental disability of childhood, occurring in 5–10% of children. The difficulties in language learning and use, put these children at risk for learning disabilities, given that learning occurs largely through language and can persist through out the school years impacting reading and writing skills too. Similarly, the regression and lack of communication on the part of children with ASD, initially seen as being a part of the unwillingness of the child to communicate or a lack of desire to communicate, is now recognized as being due to difficulties in communication, more particularly in social communication.

The change in the classificatory systems used in the Diagnostic and Statistical Manual of Mental Disorders that is commonly used by clinicians such as psychiatrists and psychologists

reflects these changes in perspective on communication issues in these *psychological/mental disorders* in its fifth edition. In the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR), communication disorders were classified as (1) Expressive language disorder; (2) Mixed receptive-expressive language disorder; (3) Phonological disorder; (4) Stuttering and (5) Communication disorder not otherwise specified (NOS). While the first two are language disorders highlighting both receptive and expressive aspects, the *phonological disorders* are equivalent to the *articulation disorders* though it has the broader connotation of speech sound processing difficulty too. Stuttering is the most common of the fluency disorders. The last category *Not otherwise specified* encompasses all other communication disorders that do not fit into any of the preceding categories.

In the DSM-5, the most recent edition, communication disorders have been defined more broadly as *deficits in language, speech, or in any behaviors affecting verbal and nonverbal communications*. In this most recent classification the language disorders (receptive and expressive) have been clubbed in one category, the phonological disorders are now termed *speech sound disorder*, stuttering has been renamed as *childhood onset-fluency disorder* and the last category of NOS is now labeled as *unspecified communication disorder*. A new subgroup labeled as *social (pragmatic) communication disorder* has been added in recognition of the increasing numbers of children who are found to have specific difficulties in communication in social situations in the absence of specific language deficits.

## IDENTIFICATION

Children learn to communicate from early infancy to adulthood beginning with the first cries right up to adulthood when they master complex rules that govern social communication. The identification of communication disorders that are comorbid with congenital birth anomalies such as cleft palate and lip or cerebral palsy is relatively straightforward. Communication disorders caused by other *hidden* congenital defects such as a hearing impairment or a mental retardation are more difficult to identify, particularly if they are mild to moderate in degree. The most difficult communication disorders to identify in early childhood are the developmental language disorders seen in conditions such as developmental verbal dyspraxia (DVD), specific language impairment (SLI), autism spectrum disorders (ASD) or social pragmatic disorders (SPD) largely, because the child appears to have normal development otherwise. Identification of communication disorders in children is further compounded by the fact that there is a fairly wide range with respect to the acquisition of early speech-language milestones, even in typically growing children.

In some children, while speech-language acquisition occurs in typical fashion in early childhood, they may lose these skills consequent to other illnesses such as encephalitis or meningitis or due to a head injury or an acquired hearing loss.

Broad guidelines in terms of *red flags* for speech-language acquisition are given in **Table 1** that may be used for an initial identification of a child who might be at risk for a communication disorder. It is important that children must be observed/screened for skills in understanding (receptive) and producing (expressive) speech.

A child who fails the above, either in terms of receptive or expressive language, should be considered at risk and screened for any possible underlying cause. While the delay in speech-language acquisition in children with cerebral palsy or Down syndrome are easily identified, many other developmental language disorders with more subtle communication disorders manifest as inattentiveness, deliberate disregard, specific issues with following

directions, usage of incomplete sentences with frequent pauses and clumsiness in organizing and expressing their thoughts.

## CLINICAL FEATURES

The distinguishing clinical features of the major subtypes of communication disorders in children, along with possible causes are listed in **Table 2** for an overview of the clinical features of these different disorders.

## Assessment

The first step in assessments for identifying a communication disorder is a complete medical check up by the pediatrician to be followed up by an audiologist and/or speech language pathologist (ASLP), who will document a case history covering medical and developmental milestones as well as family and language exposure history, to identify significant contributory factors, if any. Some common assessment procedures and tests used for children with different communication disorders are presented in **Table 3**. The list is by no means exhaustive and is provided for a general overview of the diagnostic process.

## MANAGEMENT

Procedures for management of communication disorders are generally initiated subsequent to medical/surgical intervention, where needed and feasible. Management is generally initiated with a counseling session in which the parents are counseled regarding the outcome of the assessments and the possible options for intervention, along with their pros and cons. The decision for a particular line of intervention say, oral language training versus sign language, or cochlear implant versus hearing aid, remains with the family and should be dependent on the merits and demerits of either option. While the management of the speech disorders are generally possible within a time frame of a few weeks, management of the language disorders is generally much more time consuming and can extend over months and years, given the nature of typical language acquisition and families need to be sensitized to these issues.

A ready reference for the key aspects of treatment along with examples of some well established approaches are provided for each category of communication disorder in **Table 3**. These are some of the more common lines of treatment and should not be taken as being a comprehensive statement.

Traditionally, speech language therapy services are provided on a one on one basis in outpatient clinics. These sessions are generally of 45 minutes duration with a frequency of 3-5 times a week and at times even fewer. As mentioned above outcomes for management of speech disorders can be seen and measured in shorter periods of time ranging from 4 weeks to 12 weeks. Management of language disorders and more complex communication disorders can extend over several months and years and the measurable impact is harder to document. Nevertheless, there is an emphasis on evidence-based studies for the wider acceptance of specific therapeutic approaches.

Access to speech language therapy services in India and in the Asia Pacific region as a whole is limited largely to urban middle and upper classes of society as of date. Attempts to expand services to the rural populations through community-based programs have been initiated sporadically, but have not met with much success. New initiatives such as the *Rashtriya Bal Swasthya Karyakram* (RBSK) are on the anvil, but need to be tried out.

## OUTCOME AND PROGNOSTIC FACTORS

Outcomes for children with communication disorders can be varied depending on the age of identification, consistency and

**Table 1** Red flags for identification of a child with delay in acquisition of communication skills

Age range (in months)	Understanding	Expression
0–6 months	Looks at you with interest when you talk to him	Uses vocal expression of pleasure when played with
6–12 months	Appears to listen to conversation between others	Babbles series of sounds that 'sound' like speech
12–18 months	Follows simple one step command	Asks for something by pointing/using a word
18–24 months	Recognizes names of familiar people and objects	Names 3 pictures
24–30 months	Can name objects when told their use for e.g. "Something that you cut with"	Uses two word combinations
30–36 months	Shows interest in 'how' and 'why' of things	Answers 'who' questions
36–42 months	Understands three step directions	Requests permission (verbally)
42–48 months	Understand words that relate one idea to another – if, why, when	Appropriately answers 'what- if' questions
48–54 months	Hears and understands most of what is said at home and in school	Likes to tell others about family and experience
54–60 months	Understands sequencing of events	Responds appropriately to 'how often' and 'how long' questions
60–66 months	Understands some jokes, surprises and make believe	Uses all speech sounds of his language correctly
66–72 months	Has an awareness of socially appropriate uses of communication	Remembers lines of simple poems, repeats full sentences, and expressions from others

duration of intervention, family involvement and school support. In general the earlier the identification and intervention, the better the long-term impact. While speech disorders such as articulation and voice disorders can generally be corrected within a few weeks to months, children with language disorders would need language therapy for a considerable length of time depending on severity and the age at which intervention is initiated. Family involvement and school support are crucial for generalization and sustenance of skills.

## PREVENTION

Specific measures to prevent communication disorders are few, given that many of these disorders are consequent to or coexistent with genetic conditions. The preventive measures are related to general maternal and infant health and risks at birth, as well as those that relate to the early language stimulation and environment. However, early identification of and intervention for communication disorders are of paramount importance in order to prevent the snowballing effect of a communication disorder

on a child's overall development including his education and emotional status.

To conclude, communication disorders in children is a major health issue that can and needs to be addressed. When provided consistently on a systematic basis and monitored regularly, the impact of speech language therapy services can be considerable, often making the difference in the inclusion or otherwise of the child in mainstream society. However, these services in countries like India are limited to urban areas and grossly inadequate to meet actual needs. Listed below are a few websites that may be accessed for more information on the availability of clinical services across the country (Indian Speech & Hearing Association, and National Trust) as well as the training programs (Rehabilitation Council of India).

- ISHA-Colleges that train in ASLP—<http://www.ishaindia.org/in/index.php>
- National Trust—Registered organizations [http://www.thenationaltrust.co.in/nt/index.php?option=com\\_frontpage&Itemid=1](http://www.thenationaltrust.co.in/nt/index.php?option=com_frontpage&Itemid=1)

## IN A NUTSHELL

1. About 10% of children have communication disorders.
2. Many communication disorders in children have a genetic basis.
3. Communication disorders have a wide-ranging impact on the educational, social and emotional well being of the child.
4. In the context of the increasingly important role of communication in current society, intervention is crucial.
5. Early identification and intervention have the best long-term impact for children with communication disorders, even the more severe ones.
6. Many school going children have mild undetected communication disorders that interfere in their learning.
7. Communication deficits are emerging as core underlying deficits in childhood disorders such as *learning disabilities* and *autism spectrum disorders* which were formerly not considered as *communication disorders*.
8. Many speech disorders can be corrected with speech therapy.
9. When provided with early, consistent speech—language therapy, many children with even the more severe communication disorders can be mainstreamed in regular schools.
10. Training and clinical services in speech-language therapy are now available across the country.

## Chapter 21.7

# Autism Spectrum Disorder

Monica Juneja, Rahul Jain

Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by persistent deficits in social communication and interaction, and presence of repetitive, restricted pattern of behaviors, interests and activities. It typically manifests in early developmental period, usually before 3 years of age and significantly affects the functioning of child. ASD is a lifelong disorder, though the impact can range from mild to severe and may improve or change across the person's life.

The nomenclature, diagnostic criteria and classification of this condition have been changing with time. The criteria laid down in various editions of Diagnostic and Statistical Manual (DSM) for psychiatric disorders are the most widely accepted and were last revised in May 2013 in DSM-5. In DSM-IV (1994), an umbrella term *Pervasive Developmental Disorders* was used for these disorders and included five diagnostic categories: (1) autistic disorder, (2) Asperger's disorder, (3) Rett's disorder, (4) childhood disintegrative disorder, and (5) pervasive developmental disorder-not otherwise specified (PDD-NOS). Autistic disorder was diagnosed in the presence of qualitative impairment in social interaction and communication, along with presence of restrictive, repetitive patterns of behaviors, interests or activities. The term high functioning autism was often used for children with autistic disorder who have normal intelligence. Asperger's disorder was said to be present when there is qualitative impairment in social interaction with presence of restrictive, repetitive patterns of behaviors, interests or activities, but grossly normal speech. Childhood disintegrative disorder was characterized by normal development till 2–10 years of age followed by marked regression in multiple areas of functioning.

One of the main concerns with the use of DSM-IV was the significant variation in the diagnostic labels being given amongst autistic disorder/high functioning autism, Asperger's disorder and PDD-NOS because of the overlap in symptoms and change in them over time. In DSM-5, the term *autism spectrum disorder* has replaced *pervasive developmental disorders* and there are no diagnostic categories within this disorder.

## EPIDEMIOLOGY

The currently available epidemiological data is based on diagnostic categories in DSM-IV. The estimated global prevalence of all pervasive developmental disorders is 62/10,000 with the range of 1–189/10,000. The same for autistic disorder is 17/10,000 with the range of 2.8–94/10,000. The male preponderance of autistic disorder is well known with the male to female ratio of 4:1.

There have been concerns about the rising prevalence of autism spectrum disorders. Though, some vaccines and environmental toxicants have been implicated, it is more likely to be due to expanded diagnostic criteria, increasing awareness of this condition and improved facilities for diagnosis.

## NEUROPATHOLOGY

During 1st year of life, a significant proportion of children with autism may show increased rate of head growth. However, only small percentage of children with ASD actually becomes macrocephalic. On neuroimaging, the brain overgrowth is most prominent in the frontal lobes, anterior temporal regions and may involve interconnected parietal areas, key areas responsible for language and social cognition.

Functional magnetic resonance imaging (fMRI) studies have found reduced size of the corpus callosum and reduced functional and structural connectivity between frontal and temporal regions as well as between cerebellum and other brain regions. An emerging theory is that short-range connections may be overgrown, whereas longer-range connections between different brain regions are reduced.

## ETIOLOGY

Autism spectrum disorder is considered to be a genetic disorder. Monozygotic twin concordance rate of autistic disorder is as high as 73–95%, with the sibling recurrence rate of 5–6% (much higher than the risk in general population). An association has been found between increasing parental age and increased risk, especially of *ASD with intellectual disability* and in females with nonfamilial ASD. This could be because of de novo mutations or epigenetic alterations in the germ cells, with increasing age. Fetal exposure to valproate is another important risk factor of ASD.

Around 10% cases of ASD are due to known genetic syndrome (*syndromic* autism) and are typically associated with dysmorphic features and/or congenital anomalies. The well-known syndrome in this group include fragile X syndrome, tuberous sclerosis, neurofibromatosis, untreated phenylketonuria, Angelman syndrome, Cornelia de Lange syndrome and Down syndrome. Syndromic autism shows equal male:female ratio.

New techniques like array comparative genomic hybridization (CGH), whole exome and whole genome sequencing have significantly contributed to our understanding of genetics of ASD; however genetic aberrations are identified in up to 10% of nonsyndromic cases. Array CGH studies have shown increased frequency of copy number variants (CNV) in ASD population as compared to controls (6–10% vs. 1–3%, respectively). However, the location of CNV and its functional relevance is more important than their mean number and size. Mutations in certain genes have also been linked to ASD including synaptic genes (neuroligins, *SHANK* and *neurexins*), morphogenetic and growth-regulating genes (*HOXA1*, *PTEN*, *EIF4E*), and calcium-related genes (*CACNA1C*, *CACNA1F*, *KCNMA1* and *SCN2A*).

## CLINICAL FEATURES

There is a wide heterogeneity in clinical expression of ASD and goes with the saying that “if you know one person with autism, you know only one person with autism.” The DSM-5 has described the core clinical features of ASD under two domains: deficits in social communication and social interaction; and presence of restricted, repetitive patterns of behavior, interests, or activities.

### Deficits in Social Communication and Social Interaction

Deficits in social communication and social interaction would manifest with the following symptoms:

- Deficits in social-emotional reciprocity
- Deficits in nonverbal communication used for social interaction
- Deficits in developing, maintaining and understanding relationships.

### Deficits in Social-Emotional Reciprocity

These can manifest as impaired sharing of interests, emotions and affect. This is one of the earliest deficits noted in ASD. Normal infants develop a behavior known as *joint attention*, by which they enjoy and share an event or object with other person by looking back and forth between the object and the person. This is impaired in ASD. There is also reduced or lack of imitation of other's behavior. Children with ASD often do not look or focus,

when shown an interesting object or event. They may lack or have delayed development of *protodeclarative pointing*. This refers to pointing at objects/events for the purpose of sharing interest like showing a flying kite, bird, dog, etc. This should be differentiated from *protoimperative pointing* that refers to pointing of objects for the purpose of getting the objects. Protoimperative pointing is part of nonverbal communication and is often also lacking in children with ASD. Similarly, these children may not show newly acquired toy/clothes to their family members or show a reward that he/she has received in school. Though, these behaviors may be exhibited later in life because of training or insistence by the family members. *Inability to share emotions and affect* manifests as decreased awareness or complete insensitivity to other people's emotions (sadness, happiness, etc.). They may also not like themselves to be calmed or comforted when in pain/distress. These children may laugh or cry without any apparent reason.

These children also have abnormality in social approach and may fail to initiate or respond to social interactions of other people. Abnormal social approach may manifest as going and talking to absolute strangers or pushing/pinching other people for interaction. The child may straightaway sit in the lap of a stranger or ask for things. On the other hand, some children with ASD are very clingy to their parent. Also, these children do not use social gestures like *namaste*, *salam*, *bye-bye*, etc. appropriately, though they may use them on prodding by the parent. They may also not initiate or respond to social smiles.

There is also failure of normal back and forth conversation. The child may not respond to his name when called or when directly spoken to. Verbal children with ASD may not initiate conversation on their own and it may be limited to answering the questions being asked. Those with good conversational skills may frequently deviate from the topic or may only talk about a particular topic of their interest.

### Deficits in Nonverbal Communication for Social Interaction

There is poor integration of verbal and nonverbal communication. Thus they may be saying something but their facial expressions and body language may imply something else. There is abnormality in eye contact, which may be inappropriate for the social situation. Some children may even show *gaze avoidance*, i.e., when a person tries to look in to their eyes, they will look the other way. Poor eye contact is considered to be cardinal feature of ASD, however many children with ASD have good eye contact or may even stare at people. Facial expressions are often limited. They may have expressionless face or may have same expression for example *smiling all the time*. Expressions of sadness, shyness, fear, etc. may be reduced or lacking.

Deficits in nonverbal communication may also manifest as deficits in understanding and use of gestures. They often do not point for objects with their index finger, a milestone that usually develops by end of first year. Understanding and use of other gestures like that for *yes*, *no*, *come*, *go*, *give*, etc. are also delayed or absent. Some children may show abnormal forms of nonverbal communications like pointing with the whole hand, or pointing using hand of an adult (hand over hand pointing).

Besides problems in nonverbal communication, speech is also often delayed in children with ASD, in fact, many may not acquire any speech at all. Delay in speech is often the presenting symptom in preschool children with ASD, though it is not a diagnostic feature in DSM-5.

### Deficits in Developing, Maintaining and Understanding Relationships

These manifest as difficulties in sharing imaginative play or making friends. Typically growing children of about 2 years of age develop pretend or imaginative plays like feeding a doll, making her sleep, combing her hair, copying her mother or pretending to talk on

phone. There is subtle sharing of this play with people around by looking at them to see if they are watching them and exchanging smiles with them. They may also bring over the toys to other people and ask them to join in. In next 1 year this play becomes more complex like going on a picnic, animal party, tea party, etc. which would usually have other people as partners in the game. Children with ASD often do not develop these behaviors. Some may have one or two types of imaginative play, but lack variety and there is also not much sharing. They often have difficulty in making friends, when they do, they often lack concept of friendship. They may become friends with much older kids, whom they keep following or very young kids, when they become the leaders. Some children with ASD may not show any interest in peers at all.

These children also have difficulties adjusting the behaviors to suit social contexts. Thus a child may not modify his behavior in classroom, library, other people's house or doctor's clinic vis-à-vis their home. They may not understand social cues from others and may suddenly butt in others conversation, not really knowing when to join in.

### Restricted, Repetitive Patterns of Behavior, Interests, or Activities

These may manifest as following:

- Stereotyped or repetitive motor movements, use of objects, or speech
- Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal/nonverbal behavior
- Highly restricted, fixated interests that are abnormal in intensity or focus
- Hyper- or hyporeactivity to sensory input or unusual interests in sensory aspects of the environment.

#### Stereotyped or Repetitive Motor Movements

Children with autism can have stereotyped or repetitive motor movements, use of objects or speech. They may have motor stereotypies in form of hand flapping, head banging, going in circles, spinning or walking on toes. There may be excessive stereotypic use of objects in form of lining of objects or toys, spinning of wheels of cars or stacking of utensils. Children may have stereotypic or repetitive speech in form of echolalia, pronoun reversal or idiosyncratic phrases. Echolalia refers to repetition of words or phrases. This repetition may be immediately on hearing something or may be delayed. In some children, the whole speech may consist of only echolalia, with the child repeating everything that he has heard before or seen on television. There may be pronoun reversal with child refereeing to himself as *you* or by his name instead of *I* or *me*.

#### Insistence on Sameness

There may be insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal/nonverbal behavior. The child may always insist on wearing a particular cloth or a particular color of cloth or particular pattern of clothes. This may also manifest as feeding problems. He may always insist on taking a particular way to the school. The child may get upset with the minor changes in the house or even in the way his/her mother is dressed. They may become very rigid about their daily routines and may throw tantrums or point blank refuse any change in the routine. Ritualized patterns may manifest as food being always served in a particular sequence. An older child may enter his house in a particular sequence of *steps followed by jumping*, etc. Ritualized nonverbal behavior can manifest as a particular sequence of *high-five followed by hand shaking* on meeting anybody while ritualized verbal behaviors may manifest as repetitive questioning about same thing.

### *Highly Restricted, Fixated Interests*

They may have highly restricted, fixated interests that are abnormal in intensity or focus. They may spend whole day playing with a piece of paper or pens, or collecting coins or stones or toffee wrappers. Older children with ASD may be preoccupied with a puzzle or cartoon character or may show fascination with certain letters, characters, logos, signages or train schedules. ASD children with good cognition may spend weeks studying narrow topics like robots, fishes, etc.

### *Hyper- or Hyporeactivity to Sensory Inputs*

They may have hyper- or hyporeactivity to sensory inputs or unusual interests in sensory aspect of the environment. Pain and temperature insensitivity is quite common in children with ASD. They may not show any response to a truly painful stimulus like a burn or laceration. On contrary, some children may cry incessantly after minor pain. They are often hypersensitive to certain loud sounds like that of pressure cooker, horns, but may not respond to human sounds. Some children with ASD will have excessive smelling and may smell unusual objects like books or toys. Few will even smell people around them. Some may not even tolerate usual environmental smells. They may also show visual fascination with mirrors, flashing lights, shadows or moving objects like pendulum. Some may show repeated visually scanning of their hands.

### **Other Associated Symptoms**

Beside the core symptoms described earlier, a number of other symptoms and comorbidities are present in children with ASD.

Behavior problems are quite common in children with ASD. Hyperactivity is a common presenting symptom and often a diagnosis of only attention deficit hyperactivity disorder is made, without symptoms of ASD being recognized. On contrary, some children with ASD are lethargic and may not move around much. Other common behavior problems are temper tantrums, self-injurious behaviors, aggression and irritability. Temper tantrums are often the result of unmet needs due to their inability to communicate. Self-injurious behaviors can be in form of hand biting, skin picking, head banging, or eye poking. Few children are also aggressive towards the family members or peers. Persistent irritability/crying is another common behavior problem, especially in low functioning children with ASD. These behavioral problems often lead to stress among the caregivers and also interfere with the intervention programs.

Children with ASD show a spectrum of intellectual functioning ranging from profound intellectual disability to superior intelligence. About three-fourths of children with Autism have global developmental delay or intellectual disability.

Epilepsy is another common comorbidity of ASD. Around 25% children with ASD have epilepsy. The onset of epilepsy in autism has two peaks: first before 5 years of age and another in adolescence. The type of seizures and the response to treatment are almost same as in general population. On electroencephalography (EEG), epileptiform discharges are commonly seen in those without clinical seizures, however their significance is not well understood and they do not require any treatment.

Sleep problems are present in more than 50% children with ASD. They often have frequent awakenings at night, delayed sleep time, prolonged sleep latency and early wake up time. Overall, the total sleep time is reduced in these children, however some children with ASD may sleep excessively also.

Often children with ASD show unawareness of dangers like that of height, fire or stray animals. Others demonstrate excessive fear to certain harmless objects or stimuli like soft toys, some particular people or images.

Older children with ASD may show psychiatric comorbidities like depression, low self esteem, anxiety, etc.

Occasionally children with ASD have some extraordinary skills, referred to as savant skills. They may be exceptionally good at arts, spellings, calculations or music. This is often related to their restricted interests.

### **Patterns of Onset and Early Symptoms**

There are three patterns of onset of ASD. Most of the children with ASD have symptoms from early infancy with impairments in typically seen social behaviors and communicative intent. Some children with ASD develop normally till 9–12 months of age after which the social and communication development ceases and typical features of ASD manifest. Others (around 15–25%) develop normally till about 15–18 months of age after which they show gradual regression of social and communicative milestones. These children may have started speaking few words with meanings, enjoying social play like peek-a-boo and started pointing. Subsequently regression occurs with gradual loss of speech and development of poor eye contact, social aloofness, and motor stereotypes. Many of these children with apparently normal development prior to regression actually have mild delay in social milestones from the beginning.

The symptoms of ASD seen in infancy include poor social smile and vocalization, decreased interest in people, poor eye contact, decreased response to their names, absence of stranger anxiety and poor imitation. In second and third year of life, most of the children present with delayed speech, hyperactivity or severe tantrums. They may also have poor eye contact, preference for aloofness, decreased interest in peers, poor response to being called and motor stereotypes.

### **DIFFERENTIAL DIAGNOSIS**

#### **Global Developmental Delay/Intellectual Disability**

As this is a common comorbidity in ASD, it is often difficult to differentiate it from global developmental delay (GDD)/intellectual disability without ASD, especially when the GDD/intellectual disability is in severe range. The diagnosis of ASD is considered in these circumstances when the delay in social and language domains is more than other domains and features typical of ASD are present like poor eye contact/gaze avoidance, poor listening response, social aloofness, poor use of gestures or presence of atypical gestures like *hand over hand pointing*.

#### **Attention Deficit Hyperactivity Disorder**

This is an important differential diagnosis of ASD because hyperactivity and attention problems are seen in both the conditions. Children with attention deficit hyperactivity disorder (ADHD) may manifest fleeting eye contact, because of problems in attention and poor relationship with family members and peers because of impulsivity or frequent fights but not due to lack of social interest. During assessment in one-is-to-one setting, hyperactivity and the attention problems are usually not manifest in children with ADHD. However, children with ASD are hyperactive even in the doctor's office because of impaired awareness of social context. They also show other characteristic features of ASD.

#### **Expressive Language Disorder**

This condition is quite common and presents with speech delay. However, their receptive speech, nonverbal communication and social skills are normal.

#### **Hearing Impairment**

Children with hearing impairment also present with speech delay, however their nonverbal communication and social skills are appropriate for age.

## Vision Impairment

Visual impairment results in poor eye contact. These children may also have impaired peer interaction, self-stimulatory behaviors and impaired gesture use.

## Social (Pragmatic) Communication Disorder

This is a new disorder described in DSM-5. Children with impairment in only social communication and social interaction, in the absence of repetitive or restricted pattern of behaviors or interests are given this diagnosis. As per DSM-IV, children with this symptomatology were diagnosed as PDD-NOS.

## Rett Syndrome

Rett syndrome was included in pervasive developmental disorders in DSM-IV, however this has been excluded in DSM-5, as it is now considered a neurodegenerative disorder. Females with Rett syndrome often fulfill the diagnostic criteria for ASD till preschool age group. Subsequently most of the children show improvement in their social skills and may no longer meet the criteria for ASD.

## Schizophrenia

Childhood schizophrenia is quite a rare entity, usually manifesting after 10 years of age. It can also present with impaired social interaction, problems in speech and some atypical interests and may be confused with ASD. However, there is always a period of normal development before the onset of symptoms and hallucinations and delusions are characteristically present.

## Selective Mutism

These children have normal speech but do not speak in particular situations or contexts.

## SCREENING AND EARLY DIAGNOSIS

Early diagnosis and early intervention in ASD provides the best outcome. There are certain clinical clues that can raise a suspicion in a young child. These red flag signs are:

- No big smiles or other warm, joyful expressions by 6 months or thereafter
- No back-and-forth sharing of sounds, smiles, or other facial expressions by nine months or thereafter
- No babbling by 12 months
- No back-and-forth gestures, such as pointing, showing, reaching, or waving by 12 months
- No words by 16 months
- No two-word meaningful phrases (without imitating or repeating) by 24 months
- Any loss of speech or babbling or social skills at any age.

Screening for ASD using a tool is more objective way of assessment. The American Academy of Pediatrics recommends routine use of ASD specific screening tool at 18 and 24 months of age. Various ASD specific screening tools have been developed and are used widely. A child who fails on a screening tool needs detailed diagnostic evaluation. Like all screening tools, these tools also have false negatives and false positives results.

Modified checklist for autism in toddlers (MCHAT) is the most widely used screening tool. It is designed for toddlers in the age group of 18–30 months; however it can be used as early as 15 months of age. It is modification of checklist for autism in toddlers (CHAT) and consists of 23 yes/no questions, to be completed by the parents. A child who fails on any 3 items or 2 critical items (out of the 6 critical items) needs further evaluation. MCHAT includes a follow up parental interview that increases the positive predictive value of the instrument. MCHAT has been translated in various languages including some Indian languages and is available freely.

Other screening tools that can be used in toddlers includes the Screening Tool for Autism in Two-Year-Old (STAT), Infant Toddler Checklist, The Developmental Behavior Checklist-Early Screen

(DBS-ES), Checklist for Early Signs of Developmental Disorders (CESDD) and Early Screening of Autistic Traits (ESAT).

Social communication questionnaire (SCQ), previously known as the Autism Screening Questionnaire is a good tool for children above 4 years of age. It is a parent report tool comprising of 40 yes/no questions derived from Autism Diagnostic Interview-Revised (ADI-R). There are two forms; one for less than 6-year-old and other for those above 6 years. It takes less than 10 minutes to complete and less than 5 minutes to score. The Autism Spectrum Screening Questionnaire (ASSQ) and Social Responsiveness Scale (SRS) are other tools that can be used in older age group.

## DIAGNOSTIC ASSESSMENTS

As there is no biological test for ASD, the diagnosis is based on the constellation of clinical features. The most recent diagnostic criteria have been laid down in DSM-5 by American Psychiatric Association (Available at <http://www.psych.org/practice/dsm>).

While evaluating a child with suspected ASD, a detailed history is elicited from the caregivers including their current concerns and also that of other manifestations present in ASD. Emphasis is laid on the early development of social behaviors and communication skills. Other important histories include that of associated problems or comorbidities, birth history, family history and developmental history pertaining to all developmental domains.

A general physical and neurological examination is performed. A detailed observation of the child is performed for his behavior and interaction with parents, peers, strangers and the examiners. The play of the child with various toys/objects, eye contact, speech and gesture use is also observed.

The DSM criteria does not give cut-offs for any of the behaviors, thus various objective tests have been developed to facilitate the diagnostic process. Amongst these tools, Autism Diagnostic Interview-Revised (ADI-R) and Autism Diagnostic Observation Schedule (ADOS) are considered as gold standard for research purposes. ADI-R is standard semistructured interview that is administered to the caregiver by a trained administrator. It consists of 93 questions and is suitable for children above the mental age of 18 months. ADI-R has a sensitivity of around 77% and specificity of around 63% in diagnosing Autism.

Autism Diagnostic Observation Schedule (ADOS) is a semi-structured, direct observational assessment. ADOS consist of four separate modules. An individual is evaluated on any one module based on his age, language and developmental level. In each module, a protocol of activities or social presses is administered in approximately 45 minutes and each item is scored on 4-point scale. Wide range of ASD specific characteristics like joint attention, nonverbal communication and conversational skills are assessed. ADOS has a sensitivity of around 91% and specificity of around 65% in diagnosing Autism.

Childhood Autism Rating Scale (CARS) is another tool that can be used for screening or diagnosis. The current edition (CARS-2) consists of two 15-item behavior rating scales and a questionnaire for parents or caregivers. The second 15-item rating scale was introduced later in CARS-2 and has to be administered only if high functioning ASD is suspected. CARS can be used for children of 2 years of age or above and involves parental interview and direct observation of the child. The 14 items incorporated in CARS are rated on Likert scale of 1–4. A score between 30 and 36.5 is considered indicative of a mild to moderate autistic disorder and a score of 37 or higher is indicative of severe autistic behavior. CARS has a sensitivity of around 70% and specificity of 75% in diagnosing Autism. A score of 25.5 or above has been found to have good sensitivity and specificity for diagnosing ASD.

## COMPLIMENTARY ASSESSMENTS

Assessment for cognitive functioning, adaptive functioning, maladaptive behaviors, and developmental level of speech is an integral part of assessment and helps in designing the intervention program for these children. Assessment of cognition is quite difficult

in children with ASD as there are deficits in verbal and nonverbal communication, often accompanied by behavior problems. Nonverbal intelligence scales like Mullen's scale and Leiter's scale are often useful. Vineland adaptive behavior scale (VABS) or Vineland social maturity scale (VSMS) is used to assess adaptive functioning. VABS can also assess for maladaptive behaviors. Evaluation by a speech therapist is required for assessment of receptive and expressive level of speech, nonverbal communication and presence of stereotypic or idiosyncratic use of language. Audiological evaluation should also be done in all children.

## ETIOLOGICAL EVALUATION

Diagnostic testing can identify an etiology in less than one-fourth of cases. The testing can be in form of genetic testing, neuroimaging, EEG and metabolic testing. American Academy of Pediatrics have given recommendations for testing, however the degree of evaluation depends on the available resources. Comparative genomic hybridization (CGH) or high resolution karyotyping can be offered to children with ASD, especially those with intellectual disability. These children should also be tested for fragile-X syndrome. Genetic testing for Rett syndrome (*MECP2* gene mutation) should be done based on clinical suspicion. Magnetic resonance imaging should be considered in children with regression, microcephaly, midline facial defect, neurocutaneous stigmata or abnormalities on neurological examination. EEG should be considered in presence of clinical seizures, unexplained behavior change, and presence of regression. Metabolic testing should only be considered in children with features suggestive of inborn errors of metabolism.

## MANAGEMENT

Educational intervention therapy is the mainstay of treatment for children with ASD. Over the years, many different techniques of educational intervention therapies have evolved. Out of these, programs based on Applied Behavior Analysis (ABA) are the most evidence based and practiced. Other widely known techniques are Treatment and Education of Autistic and Related Communication-Handicapped Children (TEACCH), and Pivotal response treatment (PRT). The intervention program should have some essential components as shown in **Box 1**.

### BOX 1 Essential components of an intervention program

- Start the intervention program as soon as the diagnosis is made
- It should be comprehensive addressing communication, socialization, and adaptive behaviors
- It should be individualized and be intensive, to be delivered on a daily basis (American Academy of Pediatrics recommends at least 25 hours of therapy per week)
- It should be either in one-to-one setting or involving small groups
- Parental training and involvement should also be an integral component of the program.

Applied Behavior Analysis (ABA) is based on the principle of *functional behavior analysis*. Thus, all the behaviors (actions) of the child are analyzed in detail regarding their antecedents and the consequences, for determining the function of each behavior. After this analysis, the intervention program is designed to increase or decrease any particular behavior by modifying the antecedents or consequences. The program is delivered at high intensity by a teacher in one-to-one setting.

PRT is treatment based on ABA but the treatment is delivered in natural setting of the child and the teaching/learning process is initiated by the child, with the teachers following the cues of the child.

TEACCH is a classroom based program, with essential component of structuring the environment and physical activities. Structuring environment involves organization of physical space

and predictable sequence of activities. Classroom teaching is done using visual schedules to guide the child for doing activities, which are determined by the likes of the child.

Early Start Denver Model (ESDM) is a recently launched eclectic behavior program that tries to follow the normal development of a child to deliver interventions in a naturalistic play based setting, using principles of ABA. It is designed for young children with ASD till 60 months of age. This model has shown substantial benefits in well designed research.

## Pharmacological Management

Presently, there is no drug that addresses the core deficits of social interaction and communication in children with ASD, however pharmacotherapy has a definite role in management of associated symptoms like maladaptive behaviors, repetitive movements and sleep problems. These comorbid symptoms often limit the functional abilities of the child and interfere with implementation of the early behavioral intervention program.

Maladaptive behaviors like aggression including self directed aggression, irritability, temper tantrums and hyperactivity are common targets of pharmacotherapy. Psychotropic drugs like haloperidol, risperidone, olanzapine and aripiprazole have shown moderate to large short-term benefits in controlling these behaviors. Risperidone, an atypical antipsychotic drug has been most widely studied in children with ASD. The drug is usually started in dose of 0.5 mg at night time with addition of morning dose subsequently. Increments are usually done every 3rd day by 0.5 mg/day, till the desirable effect is achieved to a maximum dose of 3.5 mg/day or significant side effects occur. Drowsiness and weight gain are the most commonly reported side effects. Other side effects are QTc prolongation, dyslipidemia, hyperprolactinemia, extrapyramidal symptoms, etc. Haloperidol, although as effective as risperidone, is less often used because of the extrapyramidal side effects. Aripiprazole is another atypical antipsychotic for treating irritability in children aged 6–17 years with ASD. It is associated with lesser weight gain and decreased risk of hyperprolactinemia. It is generally used when risperidone is not effective or not tolerated. The therapeutic dose ranges from 5 mg/day to 15 mg/day.

Methylphenidate and atomoxetine can also be used for management of inattention, impulsivity and hyperactivity symptoms in children with ASD, though the benefits are moderate. Selective serotonin reuptake inhibitors like Fluoxetine has been used in management of anxiety and depression in adolescents and adults with ASD. Sleep problems is another comorbidity that can be managed using Melatonin, however it has moderate effect in reducing sleep latency and night-time awakenings and increasing total sleep duration. It is used in dosages of 1–10 mg/day, 30 minutes before the bedtime. Other drugs used in management of sleep problems include Risperidone, Mirtazapine and Clonidine.

## LONG-TERM OUTCOME

Although there is a great heterogeneity in the gains in children with ASD, with early intensive therapy there is significant improvement in socialization and communication domains till 6 years of age, when almost 10% of children may outgrow their condition. Subsequently, there is relative flattening in gains though repetitive and maladaptive behaviors continue to improve even in adolescents and adults. Despite this improvement, very few persons with ASD achieve high level of independence. The important prognostic factors are good cognition (intelligence quotient above 50), early language development, early diagnosis, early intensive behavior therapy and management using ABA. Socioeconomic factors also impact the prognosis.

The average life expectancy of persons with ASD is only about 3 years less than the general population, the mortality is mainly related to seizure disorder and intellectual disability. Adults with ASD also suffer from wide range of psychiatric comorbidities like anxiety, depression and obsessive compulsive disorders.

### IN A NUTSHELL

1. Autism spectrum disorder is characterized by persistent deficits in social communication and social interaction, and the presence of repetitive, restricted pattern of behaviors, interests and activities.
2. ASD has very high concordance rate amongst monozygotic twins and is considered to be a genetic disorder; however the genetic determinants are mostly unknown.
3. Common clinical features seen in children with ASD are speech delay, poor eye contact, poor use of gestures, social aloofness, impaired peer interaction and stereotypic body movements.
4. Children with ASD often have associated problems like intellectual disability, behavior problems, epilepsy, and sleep problems.
5. Early diagnosis and early intensive educational interventions is recommended for all children with ASD.
6. Modified checklist for autism in toddlers (MCHAT) is the most widely used screening tool in early age. Social communication questionnaire (SCQ) can be used for screening in older age groups.
7. Diagnosis is based on the criteria laid down in DSM-5 by American Psychiatry Association. Alternatively, tools like Autism Diagnostic Interview–Revised (ADI-R), Autism Diagnostic Observation Schedule (ADOS) and Childhood Autism Rating Scale can be used for diagnosis.
8. Pharmacological agents, mainly atypical antipsychotics are used to control maladaptive behaviors.

## Chapter 21.8

# Rett Syndrome

Monica Juneja, Rajni Khajuria

Rett syndrome (RTT) is a neurodevelopmental disorder primarily affecting females, but recently has also been found in few male patients. It is the second most common genetic cause of intellectual disability in girls, accounting for up to 10% of all cases, but is commonly misdiagnosed as autism, cerebral Palsy or Angelman syndrome due to the overlap of clinical features.

## EPIDEMIOLOGY

Rett syndrome is a pan ethnic disorder with worldwide incidence of approximately 1 in 10,000 to 1 in 15,000 live female births. It generally starts in children aged 6–18 months with neurodevelopmental arrest, but characteristic clinical features become evident by the age of 2–4 years. They usually survive into adulthood, but the incidence of sudden, unexplained death is significantly higher.

## ETIOPATHOGENESIS

Rett syndrome is a genetic disorder caused by mutations in methyl-CpG binding protein-2 (*MECP2*) gene, present on X chromosome. The *MECP2* gene has four exons and codes for the *MECP2* protein, which contains four significant domains including a *methyl binding domain* and a *transcription repression domain*. Functioning as a global transcriptional repressor, mutations in this gene produce loss of function of this protein and unregulated expression of the other genes that it normally represses. *MECP2* expression is ubiquitous throughout the body, but its expression in mature postmigratory neurons is of particular importance.

*MECP2* mutations, which are mostly sporadic, account for majority of mutations in classically affected females, suggesting that these mutations are the major cause of classical RTT. There are eight most common mutations (R106W, R133C, T158M, R168X, R255X, R270X, R294X and R306C) of *MECP2* gene that account for almost 70% of all mutations. The symptoms and severity of RTT may depend on both the percentage of activated defective genes and the type of mutation. In atypical RTT, the rate of *MECP2* mutation detection is lower, but a proportion of atypical RTT cases result from mutations in a different genes such as *CDKL5*, *NTNG1* and *FOXG1*.

In families with a child with RTT, the risk of having a second child with the RTT is reportedly less than 1%. However, recurrence in families can occur through mechanisms such as germline mosaicism.

## CLINICAL FEATURES

Rett syndrome can have a classical presentation or an atypical one. Girls with classical presentation have an uneventful pre-perinatal period with a normal head circumference at birth and no dysmorphic facies. First few months are grossly normal, with development of some speech and hand functions. Though decrease in head size may start from 4 months onward and there may be some subtle features, none are severe enough to raise concerns by the family or the pediatrician. This apparently normal period is followed after 6–18 months of age with *early onset stagnation phase* (stage 1) with delay in development of milestones, most obvious as delay in independent sitting, crawling or walking. It may last for few months or a year and is followed by stage 2.

The most characteristic period of *rapid destructive stage* (stage 2) is at age 1–4 years. The onset is usually heralded by sudden onset irritability marked by episodes of excessive crying, self injurious

behaviors, aggression toward others and decreased sleep. The girls develop autistic features with poor eye contact, solitary play and characteristic midline hand stereotypies (washing, clapping, tapping, wringing, hand mouthing, hair pulling, pin rolling, clenching, clapping), preceded by loss of purposeful fine motor skills. There is gait apraxia with ataxia and evolving spasticity of limbs, breathing abnormalities in the form of episodic hyperventilation, apnea, aerophagy and valsalva maneuver and development of seizures. Breathing abnormalities usually occur only during awake state.

This phase may last for few weeks to months and is followed by 3rd phase, *Pseudostationary stage*, starting from 2 years to 10 years of age. This stage is characterized by improvement in socialization, eye contact, nonverbal communication skills and some gain in gross motor milestones with achievement of locomotion. In fact, this improvement of skills or stabilization of symptoms helps in differentiating RTT from other neurodegenerative disorders. Sleep problems, GIT problems, compulsive hand stereotypies, breathing abnormalities and seizures however continue. Seizures may appear for the first time during this phase but stereotypies may decrease later. During this stage, RTT girls characteristically have a mask like facies but are very alert, smiling and communicate with their eyes.

Many girls may continue in this stage throughout their lives, but others progress to *fourth stage of late motor deterioration*, which is characterized by development of increased rigidity/parkinsonian features, dystonia, ataxia-tremors, scoliosis and worsening of mobility. Progressive scoliosis usually appears after 10 years of age, is believed to be neurogenic and is more marked in those with more severe developmental impairment.

Although most girls with RTT would survive till adulthood but there is increased risk of sudden death. The cause is unclear but may be related to seizures, autonomic dysfunction, or cardiac conduction abnormalities, e.g. long QT intervals and cardiac arrhythmias. The clinical features of atypical RTT are given in **Table 1**.

## DIAGNOSIS

The diagnosis of RTT is clinical as typical features of RTT may be seen in the absence of *MECP2* mutations and also because these mutations may be identifiable in other conditions as well. The diagnostic criteria of RTT have evolved over time and were revised recently in 2010 (**Table 2**). Although initially recognized only in girls, boys (most commonly males with X-chromosome aneuploidy), who meet the criteria for typical RTT have also been identified and are considered to have typical RTT. Acquired microcephaly is a distinctive clinical feature of RTT, but is not included as essential criteria in the revised criteria as it is not found in all individuals with typical RTT. However, because it can alert a clinician to this diagnosis, it has been included as a feature that should raise suspicion of RTT.

It is important to remember that regression is essential feature in all types of RTT (classical and atypical) and because many patients would regain skills later on, it is essential to very carefully take history of regression of speech and hand functions in suspected cases. Some RTT cases may not show regression till 5 years of age and in otherwise typical cases without regression prior to this age, a diagnosis of probable RTT may be made.

Genetic testing should be offered to all those patients who meet the clinical diagnostic criteria for RTT.

## Differential Diagnosis

### Stage I (Early Onset Stagnation)

Benign congenital hypotonia, cerebral palsy, Prader-Willi syndrome, Angelman syndrome and other metabolic disorders are important conditions to be considered during this phase.

**Table 1** Variants of Rett syndrome

**Table 2** Revised diagnostic criteria for Rett syndrome (RTT)

<b>RTT diagnostic criteria 2010</b>
Consider diagnosis when postnatal deceleration of head growth observed
<b>Required for typical or classic RTT</b>
<ul style="list-style-type: none"> <li>A period of regression followed by recovery or stabilization</li> <li>All main criteria and all exclusion criteria</li> <li>Supportive criteria are not required, although often present in typical RTT</li> </ul>
<b>Required for atypical or variant RTT</b>
<ul style="list-style-type: none"> <li>A period of regression followed by recovery or stabilization</li> <li>At least 2 of the 4 main criteria</li> <li>5 out of 11 supportive criteria</li> </ul>
<b>Main criteria</b>
<ul style="list-style-type: none"> <li>Partial or complete loss of acquired purposeful hand skills</li> <li>Partial or complete loss of acquired spoken language</li> <li><i>Gait abnormalities</i>: Impaired (dyspraxia) or absence of ability</li> <li>Stereotypic hand movements such as hand wringing/squeezing, clapping/tapping, mouthing and washing/rubbing automatisms</li> </ul>
<b>Exclusion criteria for typical RTT</b>
<ul style="list-style-type: none"> <li>Brain injury secondary to trauma (peri- or postnatally), neurometabolic disease, or severe infection that causes neurological problems</li> <li>Grossly abnormal psychomotor development in first 6 months of life</li> </ul>
<b>Supportive criteria for atypical RTT</b>
<ul style="list-style-type: none"> <li>Breathing disturbances when awake</li> <li>Bruxism when awake</li> <li>Impaired sleep pattern</li> <li>Abnormal muscle tone</li> <li>Peripheral vasomotor disturbances</li> <li>Scoliosis/kyphosis</li> <li>Growth retardation</li> <li>Small cold hands and feet</li> <li>Inappropriate laughing/screaming spells</li> <li>Diminished response to pain</li> <li>Intense eye communication—<i>eye pointing</i></li> </ul>

**Stage II (Rapid Destructive Stage)**

At this stage, RTT must be differentiated from autism spectrum disorders, tuberous sclerosis, metabolic disorders (e.g., phenylketonuria, ornithine transcarbamylase deficiency), infantile neuronal ceroid lipofuscinosis, Angelman syndrome,

or an infectious encephalopathy. Even though, ASD occurs predominantly in males and is much more common, RTT should be considered in girls with autism spectrum disorder (ASD), especially if there is history of regression. Girls with RTT not only have loss of communication and social skills but also lose motor skills, unlike girls with ASD in whom motor skills are usually preserved. Similarly, acquired microcephaly is common in RTT, whereas children with ASD usually have increased head growth in early infancy. Even though eye contact and socialization is poor in stage II, they both significantly improve later, in fact, eye gaze is commonly used for communication in RTT. Apart from this, presence of typical hand stereotypies, gait apraxia and breathing abnormalities are usually not seen in ASD.

**Stage III (Pseudostationary Stage)**

In stage III, RTT must be differentiated from ataxic cerebral palsy, spinocerebellar degeneration, leukodystrophies, neuroaxonal dystrophy, Lennox-Gastaut syndrome and Angelman syndrome as these share some similar features with RTT.

**Stage IV (Late Motor Deterioration)**

Degenerative disorders must be kept as differential diagnosis.

**MANAGEMENT**

There is no specific medical treatment for patients of RTT except symptomatic and supportive treatment. It is very important to do an EKG as soon as diagnosis of RTT is made. Apart from medications to treat seizures, hyperactivity, sleep problems and digestion or gastric problems, it is important to avoid drugs which will depress ventilation or prolong QT interval. Comprehensive management also includes physical rehabilitation, educational as well as psychosocial support and is best provided by a team. Physiotherapy, occupational therapy and adaptive technologies have been found effective in facilitating communication, maintaining hand function and locomotion. Progression of scoliosis and the ability to walk can be managed by intensive physical therapies. Adaptive equipments like braces and arm splints have also been found very effective.

Psychosocial support for families is an integral part of the holistic approach to management, and parent support groups offer immense practical day-to-day support to families.

### IN A NUTSHELL

1. Rett syndrome is a neurodevelopmental disorder usually seen in females but has also been diagnosed in some males. It is second commonest cause of intellectual disability in females.
2. Though mutations in *MECP2* gene have been identified as etiology of RTT, the diagnosis is clinical. Some atypical cases may have mutations in *CDKL5*, *NTNG1* and *FOXP1* genes. The common atypical variants are: (i) preserved speech variant, (ii) congenital variant and (iii) an early seizure variant.
3. Classical RTT follows a typical course with stage 1 of *early onset stagnation* from 6–18 months of age followed by the *rapid destructive stage* (stage 2), the *pseudostationary stage* and *late motor deterioration stage*.
4. The rapid destructive stage is the most characteristic period and is characterized by loss of purposeful hand movements followed by distinctive midline, compulsive hand stereotypies. There is also loss of motor, communication and social skills with poor eye contact and decreased interaction, gait ataxia, seizures, breathing problems and sleep problems. Bruxism is another stereotypy which is present in more than 80% of girls with RTT.
5. The improvement of social and motor skills during pseudo stationery stage helps in differentiating RTT from other neurodegenerative disorders.
6. Many girls with RTT reach adulthood but there is increased risk of sudden death, which may be due to seizure, cardiac arrhythmias or autonomic disturbances.
7. Treatment is symptomatic. It is essential to avoid drugs that depress respiration or prolong QT interval.

## Chapter 21.9

# Attention Deficit Hyperactivity Disorder

Rajesh Sagar, Rohit Verma

Attention-deficit hyperactivity disorder (ADHD) is characterized by developmentally inappropriate motor hyperactivity, inattention and impulsiveness leading to impairment at home and school. Impairment in academic and social functioning along with skill deficits render such children to academic failures and social isolation leading to demoralization, poor self-esteem, delinquency and substance use.

Its inheritance is complex and is modulated by environmental factors with genetics playing a major role. Several gene variations involved with the regulation of dopamine, norepinephrine, and serotonin neurotransmission have been linked with ADHD. Cognitive and functional studies frequently indicate altered processing in ADHD with dysfunction of frontosubcortical networks of the brain.

The lack of an objective test makes the behavioral features and the resulting dysfunction as an important tool to diagnose the condition, which is complicated by the frequent presence of coexisting psychiatric disorders. Pharmacological treatment needs to be appended with psychosocial interventions, such as parent training and cognitive behavior therapy, for management.

## EPIDEMIOLOGY

Worldwide studies report prevalence of ADHD in children to be between 3% and 9%. The most common subtype is combined subtype with features of inattention and hyperactivity/impulsivity comprising 50–70% of all ADHD individuals. ADHD affects both genders with male to female ratio of up to 10:1 in clinics to 2–3:1 in epidemiological samples. Prevalence rates of ADHD in the Indian subcontinent vary from 5% to 15.5% with the male to female ratio ranging from 3 to 6.4:1. The Indian Council of Medical Research reported prevalence rate of hyperkinetic disorders to be 1.6% among children aged 4–16 years with higher rates in urban middle class (3.7%), than slum (1.2%) and rural areas (0.5%).

## ETIOLOGY

Attention-deficit hyperactivity disorder is highly heterogeneous and multifactorial in its etiology; proposed to be mediated by a combination of environmental and genetic factors. The genetic cause linking to dopamine deficit is considered to be the primary cause for ADHD and various acquired factors to be secondary.

## Environmental Factors

There have been numerous risk factors (Table 1) associated with ADHD but it is difficult to prove any casual association with any, many associations are linked retrospectively by reverse causation. Some of these risk factors may modify each other by gene-environment interactions.

## Genetic Factors

The mean heritability of ADHD is about 80% which suggests the role of nonheritable factors also in the etiology. Family studies have found two- to eight-fold higher rates of ADHD in affected families in comparison to their healthy unaffected relatives. Twin studies have observed higher concordance rates in monozygotic compared to dizygotic twins. Adoption studies report increased rates of ADHD in biological parents of ADHD adoptees in comparison to adoptive parents of the affected child and the parents of children without ADHD. Several genes regulating multiple neurotransmitters have been associated with ADHD (Table 2).

## PATHOGENESIS

### Neuropsychological Studies

An alteration in the corticostriatal circuitry has been implicated in ADHD. This circuit includes the dorsolateral prefrontal cortex (DLPFC) and anterior cingulate cortex (ACC), the dorsal striatum (especially the caudate nucleus) and the thalamus, linking to the cerebellum. The DLPFC has role in response inhibition, working memory, planning and organizing behavior. The ACC apart from its role in cognition and motor control, govern the arousal/drive state. Dorsal striatum modulates responses and the cerebellum coordinates motor activities and attention.

Deficits have been shown in areas of vigilance-attention and executive functioning (EF) which mainly includes: response inhibition, nonverbal and verbal working memory, self-regulation of emotion and motivation, and reconstitution (Barkley model). Response inhibition delays and interrupts responses and controls interference for controlling verbal and motor impulses. The nonverbal and verbal working memories govern the capacity for reading comprehension and moral conduct. Working memories also provide the ability to control emotions along with the motivation and persistence necessary to meet goals. Analysis of experiences in order to synthesize new responses for achieving goal is undertaken by reconstitution. Deficit in executive functioning is not a universal finding in ADHD which have led to emergence of other hypothesis involving impairments in state regulation and delay aversion contributing to the neurobiological heterogeneity.

Delay aversion is based on reinforcement and extinction processes proposing that goal directed behavior requires recurrent and effective proximal reinforcers, lack of which can

**Table 1** Environmental determinants causing attention-deficit hyperactivity disorder (ADHD)

Maternal	Prenatal factors	Smoking, alcohol intake, drug use (e.g., cocaine)
	Perinatal factors	Stress in pregnancy, maternal health (obesity, anemia, and exanthema)
	Natal and postnatal factors	Bleeding in pregnancy, protracted/complicated delivery, breech delivery, prematurity/low birthweight/ intrauterine growth restriction, low Apgar score, hypoxic-ischemic encephalopathy, small head circumference
External	Childhood illnesses	Viral infections, meningitis, encephalitis, otitis media, anemia, cardiac disease, thyroid disease, epilepsy, autoimmune disorders and metabolic disorders
	Head injury	Particularly involving the frontal lobes
	Toxins and drugs	Organic pollutants, e.g., pesticides, polychlorinated biphenyls (PCBs), lead, arsenic, aluminum, mercury and cadmium
	Nutritional disorders	Food additives, food allergies, sucrose, gluten sensitivity, and fatty acid and iron deficiencies
	Psychosocial adversities	Low socioeconomic status, low parental education, excessive criticism, bullying and family discords

**Table 2** Genes implicated in attention-deficit hyperactivity disorder (ADHD)

Candidate genes	Catecholaminergic genes	7-repeat allele of dopamine D4 receptor gene ( <i>DRD4</i> ) variant, <i>DRD4*7</i> (most robust association), <i>DRD5</i> gene, dopamine transporter gene ( <i>DAT1</i> ; <i>SLC6A3</i> ) and genes encoding dopamine beta hydroxylase enzyme, monoamine oxidase A (MAO A), <i>DRD2/3</i> receptors, and catechol-O-methyl transferase (COMT) enzyme
	Nonadrenergic genes	Alpha-2A, 2C and 1C adrenergic receptors and norepinephrine transporter ( <i>SLC6A2</i> ) genes
	Serotonergic genes	Serotonergic receptors <i>HTR1B</i> and <i>HTR2A</i> , serotonin transporter (HTT, <i>SLC6A4</i> ) and tryptophan hydroxylase genes
	Other genes	Gene associated with synaptosomal-associated protein of 25kDa ( <i>SNAP25</i> ), cholinergic genes encoding $\alpha 4$ and $\alpha 7$ subunits of nicotinic acetylcholine receptors ( <i>CHRNA4</i> and <i>CHNRA7</i> ), genes encoding glutamate receptors and brain-derived neurotrophic factor
Single nucleotide polymorphism arrays	Genes concerned in cell division, cell adhesion, neuronal migration and neuronal plasticity	
Chromosomal anomalies	Chromosomal regions containing ADHD predisposing loci-5p, 6q, 7p, 11q, 12q, and 17p	
Genetic syndromes	Fragile X syndrome, tuberous sclerosis and microdeletion syndromes such as Smith, Magenis, and Velocardiofacial (VCFS; 22q11 microdeletion) syndromes (commonly seen in inattentive subtype)	
Copy number variants	Preliminary findings have associated these chromosomal structural variants with ADHD. Their overlap has been seen with autism and schizophrenia, further supporting the neurodevelopmental theory for ADHD	

lead to inattention and impulsivity. The dual pathway model (Sonuga-Barke model) suggests simultaneous involvement of both EF and delay aversion such that the children with ADHD demonstrate aversion to delay, preferring smaller, immediate rewards in comparison to larger, delayed rewards. The cognitive energetic model proposes that deficit in attention and EF is not due to impaired cognitive resources per se but rather ascribed to deficiencies in activation, arousal, and effort controlling the allocation of cognitive resources.

### Neurochemistry of ADHD

Dopaminergic neural circuits are suggested to play a major role in altered reward processing mechanism endorsed by ADHD. Other factors implicating dopamine hypothesis are: drugs (like methylphenidate) utilized in managing ADHD act on dopaminergic synapses; linkage of various dopamine transporter and receptor genes to ADHD; and changes in brain regions activated by dopamine in imaging studies.

### Neurophysiological Studies

Few electroencephalograph (EEG) studies report increased slow wave activity (predominantly theta) in frontal region whereas others have shown decreased delta and increased beta percent power over the left hemisphere, indicating both under-arousal and over-arousal in ADHD. Event related potential (ERP) showed smaller amplitude of P300 along with a longer latency in ADHD, a finding which lacks specificity. Stimulus processing research has showed deficits in early as well as later processing.

### Structural Neuroimaging

Decrease in overall total brain size is the most consistent finding being reported. Magnetic resonance imaging (MRI) studies report of decreased right prefrontal cortex volume, reversal or loss of asymmetry of caudate nucleus volume (usually right caudate nucleus is larger than the left), lack of age-related decrease in caudate volume (usually caudate nucleus volume decreases with age in males), smaller size of globus pallidus, and decreased volume of corpus callosum. Cerebellar volume differences have also been observed.

### Functional Neuroimaging

There is evidence of decreased striatal blood flow and hypofrontality, which annul on initiating methylphenidate (MPH)

in some studies. Positron emission tomography (PET) scans associate ADHD with an abnormality in frontostriatal circuitry. Functional MRI (fMRI) studies suggest a primary dysfunction of dorsal anterior cingulate cortex (dACC), which is associated with perigenual anterior cingulate cortex (pACC) hyperactivity. Magnetic resonance spectroscopy (MRS) studies reported depletion of N-acetyl aspartate (NAA), a marker of neuronal integrity, in left DLPFC and also decreased striatal glutamate and lower NAA/creatine ratio in globus pallidus.

Both the functional and structural studies are consistent with each other in attributing frontosubcortical system in the pathophysiology of ADHD.

### NOSOLOGY AND DIAGNOSIS

Earliest description of behavioral abnormalities similar to ADHD was reported as squeal to head injury and postinfluenza encephalitis. Since then the disorder has traversed changes in its conceptualization reflected in the changing terminology, from “minimal brain dysfunction” to “hyperkinetic reaction of childhood” to “ADHD” in Diagnostic and Statistical Manual (DSM) editions and “hyperactive disorder” in International Classification of Diseases (ICD) (Table 3).

The DSM-5 suggests three presentations of ADHD: (1) combined, (2) predominantly inattentive, (3) predominantly hyperactive-impulsive; while ICD-10 hyperkinetic disorder requires both inattentive and hyperactive-impulsive behavior to formulate a diagnosis, thereby suggesting only the combined type of DSM-5 ADHD. Thus, DSM-5 identifies a broader group of children than ICD-10. DSM-5 suggests that several symptoms must be present prior to age 12 years, in comparison to 7 years as the age of onset in previous versions of DSM and ICD-10.

DSM-5 specifies the severity of disorder as mild, moderate or severe. There is also provision in DSM-5 for a diagnosis of ADHD in partial remission for grown up individuals with functional impairment, even when the required symptoms may not be all present.

### CLINICAL FEATURES

The core symptoms of ADHD are hyperactivity, impulsivity and inattention. While teachers usually complain of creating nuisance in the classrooms and deterioration of academic performance, parents report a lack of interest in activities requiring sustained

**Table 3** Tenth revised edition of International Classification of Diseases (ICD-10) criteria for hyperkinetic disorders

The research diagnosis of hyperkinetic disorder requires the definite presence of abnormal levels of inattention, hyperactivity, and restlessness that are pervasive across situations and persistent over time and that are not caused by other disorders such as autism or affective disorders.

**G1. Inattention.** At least six of the following symptoms of inattention have persisted for at least 6 months, to a degree that is maladaptive and inconsistent with the developmental level of the child:

- Often fails to give close attention to details, or makes careless errors in schoolwork, work, or other activities
- Often fails to sustain attention in tasks or play activities
- Often appears not to listen to what is being said to him or her
- Often fails to follow through on instructions or to finish schoolwork, chores, or duties in the workplace (not because of oppositional behavior or failure to understand instructions)
- Is often impaired in organizing tasks and activities
- Often avoids or strongly dislikes tasks, such as homework, that require sustained mental effort
- Often loses things necessary for certain tasks or activities, such as school assignments, pencils, books, toys, or tools
- Is often easily distracted by external stimuli
- Is often forgetful in the course of daily activities.

**G2. Hyperactivity.** At least three of the following symptoms of hyperactivity have persisted for at least 6 months, to a degree that is maladaptive and inconsistent with the developmental level of the child:

- Often fidgets with hands or feet or squirms on seat
- Leaves seat in classroom or in other situations in which remaining seated is expected
- Often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, only feelings of restlessness may be present)
- Is often unduly noisy in playing or has difficulty in engaging quietly in leisure activities
- Exhibits a persistent pattern of excessive motor activity that is not substantially modified by social context or demands.

**G3. Impulsivity.** At least one of the following symptoms of impulsivity has persisted for at least 6 months, to a degree that is maladaptive and inconsistent with the developmental level of the child:

- Often blurts out answers before questions have been completed
- Often fails to wait in lines or await turns in games or group situations
- Often interrupts or intrudes on others (e.g., butts into others' conversations or games)
- Often talks excessively without appropriate response to social constraints.

**G4.** Onset of the disorder is no later than the age of 7 years.

**G5. Pervasiveness.** The criteria should be met for more than a single situation, e.g., the combination of inattention and hyperactivity should be present both at home and at school, or at both school and another setting where children are observed, such as a clinic.

**G6.** The symptoms in G1–G3 cause clinically significant distress or impairment in social, academic, or occupational functioning.

**G7.** The disorder does not meet the criteria for pervasive developmental disorder, mania, depressive, or anxiety disorder.

Specify if:

**Disturbance of activity and attention:** The general criteria for hyperkinetic disorder must be met, but not those for conduct disorders.

**Hyperkinetic conduct disorder:** Both the general criteria for hyperkinetic disorder and conduct disorder must be met.

**Other hyperkinetic disorders**

*Hyperkinetic disorder, unspecified:* This residual category is not recommended and should be used only when there is a lack of differentiation between disturbance of activity and attention and hyperkinetic conduct disorder but the overall criteria for hyperkinetic disorders are fulfilled.

Source: World Health Organization. The ICD-10 Classification of Mental and Behavioural Disorders: Diagnostic Criteria for Research. World Health Organization, Geneva, 1993.

effort or child being constantly “out of control”. The symptoms suggestive of the disorder need to be present in two or more setting (at home, at school, during play, in social gatherings, etc.); present for at least 6 months; and must be severe enough to interfere with functioning in various settings.

### Symptoms of Hyperactivity

- Excessive fidgetiness (e.g., tapping hands or feet, squirming in seat)
- Difficulty remaining still when sitting is expected (e.g., at dinner, school, etc.)
- Excessive talking, difficulty playing quietly
- Run around a lot, always “on the go”.

### Symptoms of Impulsivity

- Impatient, difficulty waiting turns, interrupt conversations or others' activities
- Blur out inappropriate statements/answers too quickly
- Express emotions without restraint
- Act without considering consequences.

### Symptoms of Inattention

- Easily distractible, frequently switch from one task to another, forgetfulness in routine activities (e.g., homework, chores, etc.)
- Difficulty in focusing on organizing and completing an activity or learning something new in play, school, or home activities
- Avoids tasks that require consistent mental effort
- Gets easily bored, unless doing some enjoyable activity
- Misses details, makes careless mistakes, often loses belongings (e.g., pencils, toys, books)
- Seems not to listen when spoken to
- Have difficulty in following instructions as quickly and accurately as others.

These core behaviors must lead to a disturbance in functioning related to academic, social, or occupational activities for reaching a diagnosis of ADHD. The symptoms may secondarily dispose a child towards difficulty in forming friendships, peer rejection, poor self-esteem, and increased risk for depression and anxiety. The symptoms should also not be part of another psychotic disorder.

## DIFFERENTIAL DIAGNOSIS

Multiple conditions (**Table 4**) exhibiting some or the other symptoms of ADHD should be differentiated with a thorough history, observation and/or the use of a behavior rating scale. It is essential to differentiate from subtle aberrant behavior which may usually be present in normally developing children not having any impairment like short attention span in a preschool child or occasional impulsivity in a school going child.

### Approach to Diagnosis

Every child visiting the clinic should be assessed for ADHD. The evaluation comprises of medical, developmental, behavioral, educational and psychosocial perspectives. The assessment should include careful and detailed medical, social, and family history taking; clinical interviews and observation of the child with and without the parent; gathering information about functioning in child care center or school (from teachers) and at home (from parents/caregivers); and assessment for coexisting emotional or behavioral disorders. Thorough assessment generally requires multiple visits.

**Table 4** Differential diagnosis of attention-deficit hyperactivity disorder (ADHD)

Condition	Type
Developmental variations	Intellectual disability
	Giftedness
Neurologic or developmental conditions	Normal behavior of children
	Learning disabilities
	Language or communication disorders
	Autism spectrum disorders
	Neurodevelopmental syndromes (e.g., fragile X, fetal alcohol syndrome, Klinefelter syndrome)
	Seizure disorder
	Sequelae of central nervous system infection or trauma
	Metabolic disorders (e.g., adrenoleukodystrophy, mucopolysaccharidosis III)
	Motor coordination disorders
	Emotional and behavioral conditions
Emotional and behavioral conditions	Anxiety disorder
	Mood disorders
	Oppositional defiant disorder
	Conduct disorder
	Obsessive compulsive disorder
	Post-traumatic stress disorder
	Adjustment disorder
Psychosocial and environmental factors	Stressful home environment or an inappropriate educational setting
Medical conditions	Hearing or visual impairment
	Lead poisoning
	Thyroid abnormalities
	Sleep disorders (e.g., obstructive sleep apnea, restless leg/periodic limb movement disorder)
	Drug induced effects (e.g., albuterol)
	Substance abuse disorders

### Medical Evaluation

An evaluation of child and family cardiac history, dietary history and daily sleep pattern should be undertaken before initiating medications. The physical examination including a complete neurological examination should be undertaken. Regular monitoring of vital signs, height, weight and head circumference aids in assessment of medication effects.

### Developmental and Behavioral Evaluation

A thorough assessment should be conducted regarding:

- Developmental history, particularly language milestones
- Onset, duration, course, and degree of functional impact of ADHD symptoms
- Behavior at home and school—explore the behavioral excessiveness, pervasiveness, sustenance, comparison with other children, and temporal distribution.

The difficulty in collecting information may arise in situations of parental denial, minimization, manipulation, rationalization or contradictory views. Open-ended questions or questionnaires may be utilized to acquire historical information regarding symptoms. This should be compounded by direct observation of child's behavior and parent-child interactions.

**Behavior rating scales** Scales are useful for acquiring structured information of behavior, estimating symptom severity, measure treatment response and may add to the validity of the diagnosis. However, none of the global rating scales can provide a definitive diagnosis. *Narrow band scales* focus on the core symptoms of ADHD and have a high sensitivity and specificity. They have parent, teacher and patient versions. These include Vanderbilt assessment scales: can be used in children more than or equal to 4 years; Conners Comprehensive Behavior Rating Scales: validated in preschool children; and ADHD Rating Scale IV: validated in preschool children. *Broadband scales* assess a broad variety of behavioral symptoms, e.g., Child Behavior Checklist. They can help to recognize comorbid conditions and make the differential diagnosis narrow.

**Educational evaluation** Assessment of the functional impact of ADHD symptoms in academic setting should be conducted utilizing information regarding grades, absences, learning pattern, report cards, samples of schoolwork, etc. Details of parent-teacher meetings should also be sought.

**Psychosocial evaluation** It is prudent to assess the impact of symptoms on the psychosocial environment and vice versa which may provide an alternative explanation for the symptoms.

- Social responses at home and school—play activities, peer relationship, etc.
- Psychosocial stressors (death, divorce, or economical constraints in family).

**Neuropsychological testing** It may be valuable in assessing coexisting conditions (like learning disabilities), excluding other disorders, planning interventions, and charting treatment progress. It can also help to identify specific problem areas in EF like abstract reasoning, cognitive flexibility, planning and working memory. Various tests may be applied like Wechsler Intelligence Scale for Children, Wide Range Achievement Test-Revised, Differential Abilities Scale, or Wechsler Individual Achievement Test.

**Electrophysiological testing and imaging** Recently, US Food and Drug Administration (FDA) approved the first medical device based on brain function to help assess ADHD in children. This neuropsychiatric EEG-based assessment aid (NEBA) system device is a noninvasive test based on EEG technology recording different types and frequencies of brain electrical impulses (waves) given off by neurons and calculates the theta/beta ratio which has been reported to be high in ADHD. Quantitative EEG (qEEG) may also be employed for assessing prognosis. Variable resolution

electromagnetic tomography (VARETA) is a useful test to localize abnormal brain activity.

**Adjuvant evaluation** These are not routinely indicated but may aid in estimation of differential diagnosis and comorbid conditions, such as:

- Psychological development and occupational therapy evaluation (speech, language, specific scholastic skills and motor coordination developmental disorder)
- Mental health evaluation (behavioral and emotional disorders of childhood onset like anxiety, oppositional defiant disorder, conduct disorder (CD), adjustment disorder; mood disorder and post-traumatic stress disorder)
- Blood investigations for lead level (lead poisoning) and thyroid hormone levels (thyroid disorder)
- Genetic testing (fragile X syndrome, tuberous sclerosis, microdeletions)
- Polysomnography (obstructive sleep apnea or restless legs syndrome).

**Comorbid evaluation** Multiple conditions may mimic or coexist with ADHD such as CD, oppositional defiant disorder (ODD), major depressive disorder, bipolar disorder, anxiety disorders, substance-related disorders, tic disorders and learning disabilities. Common coexisting conditions reported in Indian literature are developmental delays, temper-tantrums, enuresis, tics, parental discord and parental psychiatric illness.

After the complete evaluation, a thorough discussion of the clinician with the parents is recommended regarding the child problematic behavior with its appropriate management measures which may entail implementing a *daily report card* procedure prior to initiating a medication trial or other psychosocial intervention.

## MANAGEMENT

An effective treatment strategy includes pharmacological and psychosocial approach, intervening in the personal, social, educational and occupational spheres. Before initiating treatment, clinician should discuss the myths regarding ADHD, precise information about ADHD, available treatment options, along with medication optimization and adverse effects with the primary caregiver/parent of the child. Regular follow-ups should be ensured to increase treatment adherence.

### Pharmacological Intervention

Pharmacological treatment relies on agents targeting dopamine and/or norepinephrine receptors. Stimulants imply the most extensively available first-line treatment option for ADHD. Stimulant medications should be used as supervised treatment in patients 6 years or older with no medical contraindications meeting the diagnostic criteria for ADHD. As being an activating drug, they should be given in daytime. The general rule of “start low and go slow” approach is followed during drug titration.

The most commonly used stimulants are methylphenidate (MPH), dextroamphetamine, and combination of amphetamine (AMP) and dextroamphetamine. Lisdexamfetamine dimesylate, a pro drug of AMP, remains inactive until metabolized therefore have less abuse potential and is also resistant to pH variation in gastrointestinal tract. Among the stimulants, only MPH is available in India for prescription under supervision. Stimulants are listed as Schedule II drugs, i.e., they provide desirable medicinal effects but at the same time are prone to be abused.

Other drugs approved by FDA having less abuse potential than stimulants are atomoxetine and extended release formulations of clonidine and guanfacine, which recently were approved as an adjunctive treatment to stimulant therapy for treating pediatric ADHD.

Second-line agents (off label drugs) include antidepressants such as bupropion, venlafaxine and tricyclic antidepressants particularly desipramine, nortriptyline and imipramine. Other useful agents include cholinesterase inhibitors, noradrenergic/dopaminergic agonists, and alpha-2a-adrenoreceptor agonists such as guanfacine. The role of atypical antipsychotics and antiepileptics like carbamazepine is still underway. Favorable effect of nicotinic modulators has also been observed.

Modafinil is a wake promoting agent which selectively activates the cortex without generalized effects on the central nervous system. It was declined FDA approval due to concerns over the possible development of Stevens-Johnson syndrome. It is generally prescribed in dose range of 200–340 mg once daily with children less than 30 kg and 300–425 mg in children weighing more than 30 kg.

Drug treatment is summarized in **Table 5**.

### Psychosocial Intervention

Psychosocial treatment is beneficial in cases where pharmacological treatment, despite its effectiveness, may lead to intolerable side effects. It enhances self-observation and coping skills in ADHD patients. Psychosocial treatments include psychoeducation, parent training, academic organization skill teaching and remediation, behavior modification, cognitive behavioral therapy (CBT), social skills training and individual therapy. These therapies focus on reducing ADHD-related behaviors, reinforcing desired behaviors, and developing positive habits which in turn helps to improve social relationships and overall functioning. This modality is preferred in children with age less than 6 years, mild symptomatology, uncertain diagnosis and when preferred by parents.

Behavioral parent training has been the most widespread and effective intervention being advised to preschool and school age children with oppositional and socially aggressive behavior. It utilizes principles of social learning theory teaching parents regarding positive reinforcement which include direct instruction, modeling and role playing.

CBT has been especially beneficial with coexisting anxiety, depression, and disruptive disorders but not for the core ADHD symptoms. It gives emphasis to problem solving approaches as well as emphasizes anticipation and consequences of behavior. Social skill training is one of the types of CBT.

Adolescents generally respond well to behavior techniques, academic interventions and family therapy whereas adults response better with CBT which includes psychoeducation and environmental modification strategies (problem solving, organization, activity scheduling, and replacement of dysfunctional thoughts).

Though nonpharmacological treatment plays important role in management of ADHD, the effect is modest. The most favorable treatment in general is individually tailored psychosocial treatment plus pharmacotherapy.

### Alternative Therapy

Agreeable evidence is lacking to support the beneficial effect of alternative therapies. These unproven remedies include elimination diet, herbal treatments, specific nutritional supplements, sensory integrative training, chiropractic medicine, body and craniosacral manipulation, electroencephalography biofeedback and optometric vision training.

### OUTCOME

With a family history of ADHD there are 50% increase chances of developing the disorder if either parent has ADHD or 35% chances if one of the siblings have ADHD. Symptom onset can occur at

**Table 5** Recommended pharmacological options for children/adolescents with attention-deficit hyperactivity disorder (ADHD)

<i>Medications</i>	<i>Duration of behavioral effects</i>	<i>Initial dose</i>	<i>Titration schedule</i>	<i>Maximum daily dose</i>
<i>Stimulants: Immediate release preparations</i>				
Methylphenidate	3–4 hours	0.3–1 mg/kg/day, 2.5–5 mg, 1–3 times daily	Increase by 2.5–5 mg daily at weekly intervals, split dose three times daily	60 mg
Dextroamphetamine	4–5 hours	0.15–0.5 mg/kg/day, 2.5–5 mg, 1–2 times daily	Increase by 2.5–5 mg daily at weekly intervals, split dose twice daily	40 mg
Amphetamine/ Dextroamphetamine mixed salts	4–6 hours	2.5–5 mg, 1–2 times daily	Increase by 2.5–5 mg daily at weekly intervals, split dose twice daily	40 mg
<i>Stimulants: Sustained release preparations</i>				
Methylphenidate	10–12 hours	18 mg	Increase by 18 mg daily at weekly intervals	Ages 6–12: 54 mg Ages 13–18: 72 mg
Methylphenidate ER	6–8 hours	10 mg	Increase by 10 mg daily at weekly intervals	60 mg
Dextroamphetamine SR	6 hours	5 mg	Increase by 5 mg daily at weekly intervals	40 mg
Amphetamine/ Dextroamphetamine mixed salts	8–12 hours	5 mg	Increase by 5 mg daily at weekly intervals	30 mg
<i>Nonstimulants: Second-line agents</i>				
Atomoxetine	8–24 hours	Weight ≤ 70 kg: 0.5 mg/kg/day × 3 days, then 1.2 mg/kg/day Weight > 70 kg: 40 mg daily × 3 days, then 80 mg daily All patients: Single dose after dinner or split dose twice daily with food		1.4 mg/kg daily or 100 mg, whichever is less
Guanfacine extended release	16–24 hours	1 mg/day, once daily	1 mg/day at weekly intervals	4 mg daily
Clonidine extended release	10–16 hours	single 0.1 mg tablet at bedtime	0.1 mg/day at weekly intervals	0.4 mg/day

3–4 years age, though only half the cases develop the disorder by 7 years of age and more than 90% develop by 12 years of age.

With the child reaching 4 years of age, hyperactive and impulsive symptoms starts appearing which continue to increase over next 3–4 years peaking at 7–8 years of age with emergence of inattentive symptoms. Hyperactive symptoms start declining after 7–8 years of age with almost negligible symptoms (in form of restlessness or inability to settle down) by the adolescence. On the other hand, impulsive symptoms persist throughout life.

Persistence of behavior is seen among the preschoolers who are difficult to control, have persistent inattentive and hyperactive behavior, display greater child defiant behavior or have greater parenting stress such as parent-child conflict or greater maternal directedness and negativity. Oppositional and socially aggressive behavior may appear between 6 years and 12 years of age in at least 40–70% of ADHD children which may further progress to ODD or CD symptoms in 25–45%. In middle childhood, they may develop learning disability, social skills deficits, low self-esteem and depression.

By late childhood, adaptive functioning is hampered due to deficit in executive functioning which is significantly below their intellectual ability. Preschoolers and childhood group are also more prone to recurring upper respiratory infections, asthma and allergies. In adolescence, there is greater alcohol and drug use. Overall, hyperactive individuals are also more prone to accidents.

ADHD symptoms can persist up to adulthood in 60% of children. The prevalence rate of adult ADHD is 4%. It may manifest in form of personality trait disorders, drug and alcohol misuse and antisocial behavior.

Despite their poor overall performance in comparison to non-ADHD counterparts, children with ADHD are capable of attaining high educational and vocational objectives. Many children have negligible emotional or behavioral problems by the time they reach mid-twenties.

## PREVENTION

Numerous factors have been linked as a casual factor for ADHD, so it is not possible to avoid all the factors but addressing them may reduce the risk.

*Primary prevention* includes promotion of maternal health during pregnancy, such as caution against use of alcohol and cigarette. Initiative should be taken to reduce environmental toxins like lead, mercury, and polychlorinated biphenyls. Though not accepted worldwide, an elimination diet has been proposed to lessen hyperactivity which targets artificial colorings, flavorings and preservatives. Hyperactivity has also been associated with sugary sodas and candy. Free fatty acids have some role in reducing ADHD symptoms. Children should be given clear cut age appropriate expectations with development of structured daily routine since early childhood. Though still needs approval, but preventing the child to watch television or video games may prevent ADHD. Regular physical exercise should be promoted. Couples with family history should be counseled regarding the risk of genetic loading of ADHD.

*Secondary prevention* includes early intervention of at risk children such as children with a family background of ADHD,

premature children, low birthweight babies, mothers with intake of toxic substances during pregnancy and children with serious craniocerebral traumas. Making teacher and parents to work together to identify ADHD at early stage should be a priority. Behavior management may be put forth through techniques such as focusing attention, disciplinary classroom promulgation and anger management. Monitoring of academic performance via multiple measures such as class participation and homework completion should also be incorporated. Regulation of social behavior and adequate organizational skills need to be provided.

*Tertiary prevention* is applied actively in symptomatic children with provision of pharmacological management and individual based therapy.

### IN A NUTSHELL

1. ADHD, a neuropsychologically heterogeneous condition, is among the most common disorders of childhood.
2. It is highly prevalent worldwide with a long-term course and pervasive effects.
3. Multiple factors may be responsible for its varied manifestations such as symptom dimensions, illness severity, family history of the disorder, shifting impairment between home and school setting, executive functioning deficits, comorbidity and developmental stage.
4. Recent studies provide more insight into the genetic, environmental, and neurobiological causes of this disorder, thereby, further enhancing our understanding of pathophysiologic processes, which, in turn, will bring about novel prevention and intervention strategies.
5. Although debatable, current classificatory system approaches provide reliable and valid cross cultural diagnostic criteria's for the disorder.
6. Promising pharmacotherapeutic options in form of stimulant as well as nonstimulant medications offers new options for managing ADHD.
7. Utmost treatment outcome may be achieved using a multimodal management approach employing appropriate pharmacotherapy with psychosocial intervention.
8. A pragmatic, multifaceted management based around the establishment of good working relationships with family and school should be incorporated.
9. The disorder requires a long-term therapeutic alliance among clinician and the patient along with their families improving their quality of life.

## Chapter 21.10

# Oppositional Defiant and Conduct Disorders

Rajesh Sagar, Rajeev Ranjan

Aggression, oppositionality and impulsivity are some of the most frequent behavioral problems seen at children and adolescents clinic. Our diagnostic system terms, such condition as oppositional defiant disorder (ODD) and conduct disorder (CD). These two conditions differ in terms of intensity as ODD refers to repetitive pattern of defiant, disobedient and hostile behavior toward authority figures, whereas CD is characterized by a persistent pattern of aggressive and nonaggressive rule breaking antisocial behaviors leading to considerable burden for the patients, their family and society. These conditions can also lead to impaired functioning in multiple domains in adult life. Both of these disorders are important clinical conditions because they repeatedly cause physical harm and property loss of others and also patients themselves are at risk for depressive symptoms, suicidal tendency and substance use. **Flow chart 1** depicts the developmental course and subtypes of ODD and CD.

## EPIDEMIOLOGY

The prevalence of ODD and CD is estimated to range between 2% and 16% in community settings, but is likely to be much greater in clinical settings. Prevalence estimates also vary by age and sex. ODD usually will present before 8 years of age, rarely later than early adolescence. Onset of CD occurs as early as 5 or 6 years, but usually occurs at late childhood or early adolescence. In Indian studies, reported prevalence of CD ranges from 0.2% to 11%, and that of ODD has been reported as 1.3%.

## ETIOLOGY

### Oppositional Defiant Disorder

Oppositional defiant disorder is reportedly more common in families with at least one parent with a positive psychiatric history and particularly those with ODD, CD, attention deficit hyperactivity

disorder (ADHD), antisocial personality disorder, mood disorders, and substance use disorders.

### Conduct Disorder

No single or combination of etiologies can be described as definitive. Both genetics and environmental factors can contribute. Neuro-transmitter system abnormalities, noradrenergic and dopaminergic activities, and serotonin may play a role. It is perhaps more useful and accurate to view CD etiology in terms of risk factors.

### Temperamental Factors/Child Factors

Male gender, difficult temperament, early behavioral problems, low IQ and school failure, impulsivity, emotional dysregulation, and hyperactivity.

### Familial Factors

Poor family functioning, marital discord, child abuse and neglect, poor parenting (harsh, inconsistent, lack of supervision), parental rejection, large family size, frequent changes in caretakers and psychiatric diagnosis in parents.

### Environmental Factors

Poor quality of schooling, socioeconomic disadvantage, peer rejection, association with delinquent peer groups, exposure to violence.

## DIAGNOSIS

### Oppositional Defiant Disorder

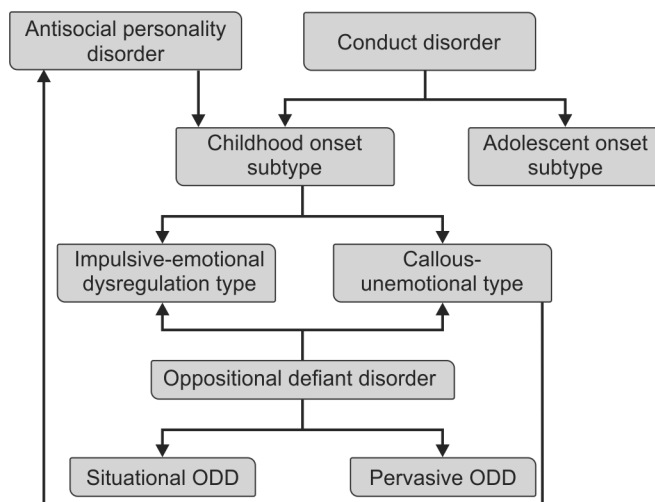

To diagnose children with ODD, there are eight possible symptoms in Diagnostic and Statistical Manual of Mental Disorders, Fourth edition (DSM-IV), from which four or more must be present during the past 6 months with suitable frequencies. These symptoms include loss of temper; argument with adults; actively defying an elder's requests; deliberately irritating others; blaming others for own mistakes; being moody or easily upset; being angry and offended and being mean or hurtful to others. ODD must not be diagnosed if the youth meets diagnostic criteria for CD or antisocial personality disorder (APD).

ODD and conduct disorder is placed in separate new section called disruptive, impulse control and conduct disorder in DSM 5. Four changes have been made to the criteria for ODD. First, symptoms are now grouped into three subtypes: (1) irritable mood, (2) argumentative or defiant behavior and (3) vindictiveness. Second, the exclusion criterion for conduct disorder has been deleted. Third, frequency typically needed for a behavior to be considered symptomatic of the disorder is provided, because many behaviors associated with symptoms of ODD occur commonly in normally developing children. Fourth, a severity rating has been added to the criteria. ODD is included in subtypes of conduct disorder in International Classification of Diseases (ICD 10).

### Conduct Disorder

DSM-IV lists 15 criteria or symptoms grouped into 4 major categories: (1) aggression to people or animals, (2) destruction of property, (3) deceitfulness or treachery, (4) serious violations of rules. Aggression to people or animals includes bullying, threatening and often indulging in physical fights with others; using any blunt or sharp object as a weapon that can cause serious physical harm to others; being physically cruel to people or animals; stealing with actual confrontation of victim and forced sexual activity (eight symptoms). Destruction of property comprises deliberate fire setting with intention of causing serious damage to others and deliberate destruction of someone's property, other than fire setting (two symptoms). Deceitfulness or

**Flow chart 1** Developmental course and subtypes of oppositional defiant disorder and conduct disorder

treachery involves breaking into a house, building or car; lying to obtain goods or favors and stealing nontrivial value items without breaking or shoplifting (three symptoms). Serious violations of rules symptom list consist of staying out at night (running away overnight is defined as running away at least two times from home while living in parental or surrogate parental home or only once, but for a lengthy amount of time) and skipping school despite parental prohibitions and it should begin before age 13 (two symptoms). Three (or more) of the criteria or symptoms should have been present for the last 12 months, with at least one criterion or symptom must be present in the past 6 months for diagnosis of CD. Conduct disorder is classified as mild, moderate and severe according to severity of symptoms.

The symptoms in ICD-10 are uniform across the subtypes of CD (**Table 2**) that also includes ODD. Criteria for diagnosis require presence of more than three symptoms from the listed symptoms (**Table 1**), of which at least three must be from items 9–24, and at least one of the symptoms from items 9–24, must have been present for at least 6 months. Difference lies in subtypes of conduct disorder, in (a) whether normal peer relationships are maintained (socialized vs. unsocialized conduct disorder) and (b) whether conduct disturbance is limited to the family context.

Oppositional defiant disorder requires presence of four or more symptoms from the listed symptoms (**Table 1**), of which no more than two are from items 9–24 (**Table 1**). The symptoms must be maladaptive and inconsistent with the developmental level. At least four of the symptoms must have been present for at least six months.

**Table 1** Item/symptom lists in ICD 10 for diagnosis of ODD and CD

Item number	Items/symptom lists
1–8	<ul style="list-style-type: none"> <li>• Unusually frequent or severe temper tantrums for the child's developmental level</li> <li>• Often argues with adults</li> <li>• Often actively defies or refuses adults' requests or rules</li> <li>• Often, apparently deliberately, does things that annoy other people</li> <li>• Often blame others for one's own mistakes or misbehavior</li> <li>• Often touchy or easily annoyed by others</li> <li>• Often angry or resentful</li> <li>• Often spiteful or vindictive</li> </ul>
9–24	<p>Frequent and marked lying (except to avoid abusive treatment), excessive fighting with other children, with frequent initiation of fights (not including fights with siblings), uses a weapon that can cause serious physical harm to others (e.g., a bat, brick, broken bottle, knife, gun), often stays out after dark without permission (beginning before 13 years of age), physical cruelty to other people (e.g., ties up, cuts or burns a victim), physical cruelty to animals, deliberate destruction of others' property (other than by fire-setting), deliberate fire-setting with a risk or intention of causing serious damage, at least two episodes of stealing of objects of value (e.g., money) from home (excluding taking of food), at least two episodes of stealing outside the home without confrontation with the victim (e.g., shoplifting, burglary or forgery), frequent truancy from school beginning before 13 years of age, running away from home (unless this was to avoid physical or sexual abuse), any episode of crime involving confrontation with a victim (including purse snatching, extortion, mugging), forcing another person into sexual activity against their wishes, frequent bullying of others (i.e., deliberate infliction of pain or hurt including persistent intimidation, tormenting, or molestation), breaks into someone else's house, building or car</p>

Comorbid diagnostic categories are hyperkinetic CD (Individual meets the diagnostic criteria for attention-deficit hyperactivity disorder and CD), depressive CD (individual meets the diagnostic criteria for CD and one of the mood disorders) and mixed disorders of conduct and emotions (individual meets the criteria for CD and additional neurotic, stress-related or somatoform disorder according to the ICD-10 criteria).

## Comorbidity

The prevalence rate of ADHD in youth with severe conduct problems (CPs) in clinic setting is about 90%, whereas this rate is 36% in community samples. CD and ODD are also associated with internalizing problems, such as anxiety and depression. One-third of children in community setting and three quarters of clinic referred children with CD have comorbid depressive disorder. However, internalizing problems has been primarily linked to ODD. Suicidal ideation and attempts are greater in CD. Studies have shown that CD comorbidity with learning disorders may be as high as 50% to 70%. Even in the absence of a learning disorder, those with CD often experience academic and other school-related difficulties. Other psychological characteristics may include decreased self-esteem, irritability, low frustration tolerance and anger outbursts. Excessive risk-taking and increased accident rates are also found in CD.

## MANAGEMENT

### Assessment

Active probing for each of the DSM 5 or ICD 10 symptoms of CD is required, when interviewing the patient and other informants. Assessment should further address important issues regarding the presence of comorbid disorders including ADHD, anxiety and mood disorders, learning difficulties and substance use disorders in adolescence. All structured psychiatric interview schedules (i.e. K-SADS, [Kiddie-Schedule for Affective Disorders and Schizophrenia] CAPA, DISC) have well-organized sections for the assessment of CD. Several specific scales are also available for assessment of symptoms of CD and ODD. Their discussion is beyond the scope of this chapter.

### DIFFERENTIAL DIAGNOSIS

Although CD can present with any or all of the features of ODD, it can be differentiated from ODD by the presence of its clearly defined more serious forms of violation of rights of others, age appropriate norms and societal rules and regulations. When both diagnoses are met, CD preempts an additional diagnosis of ODD. If ADHD is the only disorder present, it will not cause nor will its symptoms violate norms and rules in the manner of CD. In some instances, one must determine whether a behavior exhibited occurs as a result of the impulsive and inattentive symptoms of ADHD. CD symptoms may also occur along with a mood disorder. Isolated events of conduct, not meeting criteria for CD diagnosis, should be given a diagnosis of child or adolescent antisocial behavior. Disruptive behavior disorders may also be present in some cases. Differential diagnosis of ODD and CD is summarized in **Table 2**.

### Treatment

#### General Approach

To be effective, treatment must be multimodal, involve a family-based and social systems-based approach, to address multiple locus and to continue for substantial periods of time. Treatment should start with informing the patient and his parents/caretakers about the disorder and its potential complications and long-term

**Table 2** Differential diagnosis of oppositional defiant disorder and conduct disorder

<i>Oppositional defiant disorder</i>	<i>Conduct disorder</i>
Conduct disorder (by DSM-IV criteria; cannot be diagnosed both, but DSM 5 allows both diagnosis)	Oppositional defiant disorder
Attention-deficit/hyperactivity disorder	Attention-deficit/hyperactivity disorder
Impaired language comprehension (e.g., hearing loss, mixed receptive-expressive language disorder)	Mood disorders
Mental retardation	Child or adolescent antisocial behavior (V code; isolated events of conduct, not meeting criteria for CD diagnosis)
Mood disorders (including bipolar disorder)	Antisocial personality disorder
Normal individualization (in adolescence)	Pervasive developmental disorders and mental retardation
Psychotic disorders	Neurotic stress related and somatoform disorder (Mixed disorder of conduct and emotion)

sequelae. Treatment strategies should be targeted to identify comorbid disorders, such as ADHD. Pharmacological management is usually not the first choice, but should be considered in those patients who have previously failed to respond to other interventions and show escalating levels of dangerous aggression and violent behavior. Additionally, pharmacotherapy is more effective when administered in combination with psychosocial/behavioral treatments.

### Psychological Interventions

Treatment outcome studies have recognized three effective treatments for CD. These include various behavioral management strategies, parenting interventions, and cognitive-behavior skills building programs.

*Behavioral or contingency management programs* has four basic mechanism: (1) To define a clear behavioral target that figure a child behavior in specific area of concern; (2) To monitor the child progress toward achieving these target; (3) To strengthen suitable steps toward achieving these target; and (4) To identify and to grant consequences for inapt behavior. These programs have been found to be effective for altering inappropriate behaviors in different settings (e.g. home, school).

*Parent management training (PMT)* Parent management training teaches consistent parenting, positive and less harsh discipline practices, monitoring of the child and positive feedback for the child. Parent management training programs focus on structured contingency management programs at home, improving the quality of parent-child interactions and to use more effective discipline strategies, to increase positive prosocial behaviors, to strengthen parents supervising. Among all psychological intervention for children with conduct disorder, the efficacy of parent training has been the most consistently reported.

*Cognitive-behavioral skills building approach* Social-cognitive and social problem-solving deficits in children and adolescents with conduct problem are targeted by this intervention. In these deficits, children with CPs tend to think their violent behavior will

lead to positive results and this cognitive error makes them more likely to select belligerent choices when solving peer conflict. These programs inhibit impulsivity or recklessness, by training them to internalize a sequence of problem-solving steps and to adapt alternative responses and overcome deficits in the way they process social information.

### Multisystemic Therapy

It focuses on child's strength and difficulties in relation to wider social environment than intrinsic deficit. Thus, the intervention focuses on using various systemic strengths (e.g. support of grandmother or prosocial peers, etc.) for promoting responsible behavior which requires a balanced effort from both child as well as family members.

Multisystemic therapy, functional family therapy and multidimensional treatment foster care are programs developed for the treatment of aggression in older children and adolescents with juvenile justice involvement. These programs have shown effectiveness in the treatment of aggressive and violent adolescents, resulting in decreased arrest rates. In juvenile justice system, replacement home may be indicated. In India, observational home are available for these children (Juvenile in conflict with law) in bigger cities running with help of NGO.

All these psychosocial treatment approaches; however, have serious limitations. The effectiveness of PMT (parent management training) declines with increasing age with strong evidence for efficacy limited to younger children (up to around 8 years of age). Further, after therapy has been completed, the generalization of treatment benefits is low. Dropout rates are high, and parental psychopathology and lack of motivation of parents are serious obstacles in administering these interventions. Finally, these psychosocial treatments appear to bring greater benefits to children with high levels of impulsive aggression, whereas children with high levels of callous unemotional (CU) traits tend to be rather unresponsive to these interventions.

### Medical Interventions

Psychostimulants such as methylphenidate, atomoxetine, amphetamine are used to treat aggression/oppositional defiant symptom in the context of CD and ODD as a comorbid condition with ADHD. Apart from psychostimulants, risperidone amongst the second generation antipsychotics is the most widely studied medication for the treatment of aggression and conduct symptoms in children and adolescents. Lithium and carbamazepine are found to be effective in reducing aggression associated with CD. Treatment algorithm for single diagnosis of ODD/CD and comorbid diagnosis with ADHD is provided in

**Table 3.**

### Prevention

Interventions that have proven effective in treating early emerging CPs in young children target early during preschool years in growing up phase. Researched programs which are effective named triple P (positive parenting program) and incredible year parenting series. These programs are most suitable for those parents whose children are at greater risk of developing emotional or behavioral problems because of number of risk factors and identifiable symptom check list. School-based programs are also effective to identify antisocial behavior or delinquent peer groups at school and provide adequate support. Family physicians have also greater role in identifying early cases of ODD when parents report an excessively quarrelsome, disobedient, aggressive and hostile child. Other programs named intensive home visiting support services and child centered preschool stimulation program are effective in preventing early emerging conduct problems.

**Table 3** Treatment algorithm for oppositional defiant disorders (ODD) and conduct disorders (CD)

<b>Step 1</b>	Clinical evaluation to rule out psychiatric comorbidity and if required, use a general psychopathology screening and rating scale or a structured interview.
<b>Step 2</b>	In the absence of psychiatric comorbidity, psychosocial interventions should be first treatment option for ODD/CD.
<b>Step 3</b>	<ul style="list-style-type: none"> <li>• If no response from psychosocial interventions within first 3 months, either psychostimulants or atomoxetine can be tried.</li> <li>• If no response to the first medication, a second medication from a different class can be tried.</li> <li>• If the first two trials were with psychostimulants and an adequate response is not achieved, then a trial with atomoxetine is indicated.</li> </ul> <p><b>Note:</b></p> <ul style="list-style-type: none"> <li>• If aggression is the primary symptom, the first two trials should be either a methylphenidate or amphetamine.</li> <li>• If compliance is the issue, long-acting medications are recommended, to be supervised by family members.</li> </ul>
<b>Step 4</b>	Children and adolescents with serious behavioral problem like aggression, not responded to either psychosocial interventions or psychostimulants/atomoxetine, can be considered for a trial with risperidone.
<b>ODD/CD + ADHD</b>	Children and adolescents with ODD/CD and comorbid ADHD, if aggression is primary clinical symptom; either methylphenidate or amphetamine should be tried first, followed by risperidone.

## IN A NUTSHELL

1. Conduct disorder is strongly associated with significant dysfunction in the scholastic, social and work related domains leading to imperative burden for the patient, family and immediate environment.
2. Oppositional defiant disorder and CD as an individual diagnosis are placed in separate new section called disruptive, impulse control and conduct disorder in DSM 5, while in ICD 10, ODD is a subtype of CD.
3. Childhood-onset CD and high levels of CU traits are associated with severe and stable antisocial behavior associated with APD in adulthood.
4. Nonmedical psychosocial interventions are recommended as the first option for the treatment of CD.
5. There is a role for medication in the treatment of comorbid syndromes or in case of insufficient response to psychosocial interventions and severe aggressive behaviors.
6. Research on temperamental risk factors early in life can determine protective factors that help in reducing antisocial behavior later in development.

## Chapter 21.11

# Learning Disabilities

Nandini Mundkur, Chitra Sankar

A learning disability (LD) is a neurobiological disorder that presents as a serious difficulty with reading, arithmetic, and/or written expression that is unexpected for the individual's intellectual ability. These disorders can have significant impact on the child's academic and emotional development.

The learning problems significantly interfere with academic achievement or activities of daily living that require reading, mathematical or writing skills. Besides the integral difficulty in learning, it is seen that the family, school, sociocultural milieu and education play a significant influence in the ultimate outcome of learning in children. Therefore, LD is diagnosed when the individual's achievement on individually administered, standardized tests in reading, mathematics or written expression is substantially below that expected for age, schooling and level of intelligence.

### DEFINITION

Specific LDs can be defined as *a category of developmental disabilities characterized by difficulty learning in one or more areas despite otherwise typical neurological, physical, and emotional development, and adequate experiential and educational opportunities*. Another widely accepted definition is: LD is a generic term that refers to a heterogeneous group of disorders manifested by significant difficulties in the acquisition and use of listening, speaking, reading, writing, reasoning or mathematical abilities. These disorders are intrinsic to the individual and are presumed to be due to a dysfunction of the central nervous system (CNS). Even though a LD may occur concomitantly with other disabling conditions (e.g., sensory impairment, mental retardation, social-emotional disturbance) or environmental influences (e.g., cultural differences, insufficient/inappropriate instruction), it is not the direct result of those conditions or influences.

### Terminology

*Dyslexia* refers to disorder of reading, *dysgraphia* means disorder of writing and *dyscalculia* is a disorder in mathematics. Frequently a child may have a combination of one or more difficulties. Rarely do they occur in isolation.

*Dyslexia* is a specific language-based disorder characterized by difficulties in accurate or fluent word reading, usually reflecting insufficient phonological processing abilities. These difficulties in single word decoding are often unexpected in relation to age and other cognitive and academic abilities; they are not the result of generalized developmental disability or sensory impairment. *Dyslexia* is manifest by variable difficulty with different forms of language, often including, in addition to problems reading, a conspicuous problem with acquiring proficiency in writing and spelling.

*Dysgraphia* is a writing disability in which a person has difficulty expressing thoughts on paper and is associated with unreadable penmanship and problems in gripping and manipulating a pencil.

*Dyscalculia* refers to a mathematical disability in which a person has unusual difficulty solving arithmetic problems and grasping math concepts manifesting as difficulty in mathematical operations such as addition, subtraction, multiplication, division, with poor retention and retrieval of mathematical concepts.

Diagnostic and Statistical Manual of Mental Disorders-5th edition (DSM-5) labels this group of disorders as *specific learning*

*disorder* with impairment in reading, or with impairment in written expression, or with impairment in mathematics.

### PREVALENCE

The prevalence of LD depends upon the definition and varies from study to study. Dyslexia is perhaps the most common neurobehavioral disorder affecting children, with prevalence 5–17.5%. Previously, it was believed that dyslexia affected boys primarily; however, more recent data indicate similar numbers of affected boys and girls. Prevalence rates for reading disorder are estimated at 4% of school-age children, with a range of 2–10. International epidemiological studies report a prevalence of 4–17% for dyslexia, 2–8% for dysorthography and 1–5% for dyscalculia.

### NEUROBIOLOGICAL BASIS OF LEARNING DISABILITIES

Several chromosomal, genetic, inherited, teratogenic and intrauterine factors like maternal malnutrition, exposure to irradiation, TORCH infections (Toxoplasmosis, Other (syphilis, varicella-zoster, parvovirus B19), Rubella, Cytomegalovirus and Herpes infections) and substance abuse have been associated with varying degrees of learning and cognitive impairments. Disorders of cerebral dysgenesis and inborn errors of metabolism; perinatal causes like placental insufficiency, prematurity, complications of labor and delivery; postnatal causes like CNS damage due to trauma, infections, malnutrition, resistance to thyroid hormones, abuse, neglect, toxin exposure, uncontrolled seizures and neurodegenerative disorders are other causes.

Advances in imaging and electrophysiological studies have made it possible to study differences in the brains of reading impaired and reading nonimpaired individuals. In the left hemisphere of the brain, an anterior system in the region of inferior frontal gyrus believed to serve articulation and word analysis and two posterior systems—one in the parietotemporal region for word analysis and a second region in the occipitotemporal region for automatic and fluent reading of words—have been identified as neural systems for reading. In children with dyslexia, the posterior systems are found to be less activated during reading. Compensatory systems have been found to develop in right and left inferior frontal gyrus. This pattern of underactivation in left posterior reading systems is referred to as neural signature for dyslexia.

### GENETICS OF LEARNING DISABILITIES

Twin studies, sibling analysis and family pedigree analysis have shown a genetic basis for LDs. For example, twin studies have shown that if one twin has reading disability, the probability of its occurrence in the other twin is 68% for monozygotic twins and 40% for dizygotic twins. Familial transmission is known to occur. For example, if there is family history of reading disabilities, the probability of its occurrence is significantly increased. The relatives of children with learning disorders have a relatively high incidence of expressive language disorder. Linkage studies implicate loci on chromosomes 6 and 15 in reading disability. Additional findings of the strong heritability of phonologic awareness suggest that it may be the main proximal cause of most genetically based deficits in word recognition, and thus it may be the most appropriate focus for diagnosis and remediation.

### SIGNS OF LEARNING DISABILITY

Children with learning difficulties may present with poor school performance but more commonly present with school phobia or school absenteeism and somatic complaints. The earliest pointer

to a child with LD may be language delay. Other signs in preschool children are delay in learning the alphabets, difficulty in learning nursery rhymes, learning numbers, mispronunciations and difficulty in letter-sound associations. They may also have delay in fine motor skills which would later have implications for writing skills. In the primary school, there may be delay in learning to read common one syllable words such as *cat* or *bat* or difficulty in reading common irregularly spelled words, e.g., *two* or *know*; slow and hesitant reading characterized by word substitutions, omissions, guessing of words and poor comprehension. In later classes, they may read simple words easily but would skip parts of long syllable words, e.g., *aminal* for *animal* or *pictures* or *comfortable*. Children in middle grades may also have poor comprehension even when they can read fast and accurately. Problems in reading may be accompanied by writing difficulties. Handwriting may be illegible, messy with reversals and inconsistencies in the formation, sizing and spacing of letters. It is usually slow and laborious with spelling errors.

This may be accompanied by poor performance in arithmetic, computations and difficulty in solving word problems. One of the hallmarks of dyscalculia is the persistent use of effortful calculation strategies (such as using finger counting) when typically developing peers have shifted towards retrieving the solutions to calculation problems from memory. More recently, studies have shown that children with dyscalculia may also have difficulties with number sense, the ability to quickly understand, approximate and manipulate numerical quantities. It has been found that dyscalculia is associated with difficulty estimating the number of objects in a group, and comparing quantities, particularly when represented in a symbolic format (e.g., Arabic numerals).

Other signs may be fine motor incoordination, visuospatial difficulties and behavior, memory and attention dysfunctions varying from mild to severe. During adolescence, the presenting features may be behavioral problems such as aggression, truancy, school refusal, psychosomatic complaints and symptoms of stress and anxiety accompanied by poor scholastic achievement.

There is a high incidence of language impairment among those identified as dyslexic (19–63%) and vice versa there is also reading impairment among those identified with specific language impairment (SLI) (12.5–85%). In two twin studies, rates of reading impairment were significantly higher than matched control groups in children with SLI. Generally high rates of comorbidity have been reported for dyslexia and dyscalculia ranging from 17% to approximately 60%.

## ASSESSMENT OF LEARNING DISABILITY

When LD is suspected, the child is referred for complete physical, neurological and neuropsychological assessments. In general, most children do not show any neurological impairment except some may exhibit soft neurological signs. There is no single examination for eliciting subtle signs, but a number of overlapping examinations are performed such as lateral preferences, stressed gaits, gait/steadiness, sustentation postures/stations, finger to nose, tongue protrusion, maintaining eye closure, balance, hopping, and timed coordination. Assessments should be made for visual and hearing impairments.

Neuropsychological assessments include a variety of tests of abilities and functions in the domains of cognitive/intellectual, language, visual-perceptual, academic, motor, sensory, and emotional/behavioral. A correlation is then drawn between a profile of strengths and weaknesses and known brain functions.

### Neuropsychological Testing

Standardized tests are administered by a clinical psychologist. Intellectual functioning can be measured yielding an intelligence

quotient (IQ). Commonly used tests are Wechsler Scale of Intelligence-Revised (in India, the Wechsler test is adapted as Malin's Intelligence test for Indian children), Binet-Kamat Intelligence Scale. Copying geometric figures, Goodenough Draw-a-Person Test, Kohs Block Design and geometric puzzles may be used as screening tests for visual-motor coordination. Assessments of adaptive functioning can be done with Vineland Adaptive Behavior Scales.

One of the commonly used criteria for diagnosis of LD is ability-achievement discrepancy and for assessing the achievements in academic skills various tests are available, e.g., Woodcock-Johnson-III, *Wide Range Achievement Test-4* (WRAT4) and some curriculum-based Indian tests like National Institute of Mental Health and Neurosciences (NIMHANS) specific LD Index, *Grade Level Assessment Device* (GLAD) and the test by Sholapurwala. The test by Sholapurwala is available for children till 10th standard. Though Woodcock-Johnson-III, WRAT4 are validated tests, they have not been standardized for Indian population. Although the DSM-5 has specified a cut-off of at least 1.5 standard deviations (SDs) below the population mean for age on one or more standardized test, it has allowed a more lenient threshold of 1.0–2.5 SDs. Below mean, based on clinical judgment, when LD is suspected from academic history, school reports or test reports.

### Woodcock-Johnson-III Tests of Achievement

Woodcock-Johnson-III Tests of Achievement is an individually administered, comprehensive test of academic achievement and scholastic aptitude for individuals between age 2 years and 90 years. It provides age-based norms by month from ages 24 months to 90+ years and grade-based norms for kindergarten through 12<sup>th</sup> grade, 2-year college and 4-year college including graduate school. It measures academic achievement in broad curricular areas of reading, mathematics, written language, oral language and knowledge. The Standard Battery (form A or B) consists of tests 1 through 12 and test-letter-word identification, reading fluency, passage comprehension, story recall, understanding directions, calculations, math fluency, applied problems, spellings, writing fluency, writing samples, story recall delayed, handwriting legibility scale. After calculating the raw score, estimated age and grade equivalent scores are obtained by using the scoring tables.

### Grade Level Assessment Device

Grade Level Assessment Device was developed by Jayanthi Narayan for the National Institute for the Mentally Handicapped (NIMH) in 1997. It was standardized on 1,197 children from four schools from Andhra Pradesh and one school from Delhi. It assesses for english, hindi and mathematics for grade level 1–4. Oral reading, silent reading, reading comprehension, writing, arithmetic computation and arithmetic reasoning are tested. After calculating the percentage marks obtained by the child, he/she is finally classified as independent (> 70%), instructional (40–70%) and frustational (< 40%).

### Wide Range Achievement Test-4

The WRAT4 is a norm-referenced test that measures the basic academic skills of word reading, sentence comprehension, spelling and math computation. It is used for a quick, simple, psychometrically sound assessment of important fundamental academic skills. It is more valuable in the initial evaluation of children referred for learning, behavioral or vocational difficulties. The results of this test by themselves are not intended to provide formal identification of learning or cognitive disorders. Although the WRAT4 is administered individually, some of the subtests or sections of subtests may be administered to small groups of up to 5. The interpretation of WRAT4 scores has been enhanced by the

addition of grade-based norms, thereby increasing the usefulness of the test. The age-based norms are applicable from 5 years to 94 years so that the basic literacy skills of older adults could be assessed.

### Neuropsychological Assessment

A neuropsychological evaluation is important to evaluate the specific functions that are often involved in LDs such as auditory-linguistic abilities, visual abilities, memory, processing speed, cognitive efficiency and reasoning apart from assessing attention and motor and sensory abilities. This assessment is very important determining the critical areas for intervention. NEPSY-II is one such comprehensive instrument designed to assess neuropsychological development in preschool and school-age children.

### Neuropsychiatric Comorbidities

Difficulties in psychosocial adjustment appear to be the major social-emotional manifestations of LDs. Children with LD experience less acceptance, lower popularity, more peer rejection and increased neglect by peers than do normally achieving children or low-achieving peers.

It has been estimated that 30–70% of children with LD will experience ongoing comorbid symptoms of attention-deficit/hyperactivity disorder (ADHD) as they enter into adulthood. Both LD and ADHD have a high degree of comorbidity with other neuropsychiatric disorders like depression, conduct disorder, anxiety disorder, substance abuse, Tourette syndrome, tic disorders and other stereotypic movement disorders, and sleep disorders. These facts stress the need for screening, early detection, recognition, comprehensive assessments and early intervention or even incorporate prevention strategies and thus improve the quality of life of the affected individuals.

### MANAGEMENT

All the available facts and diagnostic studies are assembled and reviewed in the management of a child with LDs. A set of diagnoses and diagnostic formulations are generated. It is important to take into account the child's areas of strengths and areas of weaknesses. The strengths have to be capitalized on and the weaknesses have to be supported or strengthened. An individualized treatment plan is developed. Treatment should be multimodal and judiciously utilize medical intervention, psychopharmacological treatment, behavioral management, and educational and remedial teaching. Parent support groups and advocacy organizations also have a very important role to play. A multidisciplinary approach has to be taken to provide the most effective and efficient therapeutic care. The team would ideally comprise of developmental pediatrician, neuropsychiatrist, psychologist, remedial teachers, physiotherapist, occupational therapist, speech and language therapist, and the school. Other professionals may need to be consulted depending on the nature of the problem.

### Remedial Education

Remedial education is the focus of management. This has to be individualized and tailored to each child keeping in mind the child's various strengths and weaknesses. Reading proficiency depends on phonological processing and awareness and understanding of the alphabetical principle. A large body of evidence has been reviewed by the National Reading Panel commissioned by the National Institute of Child Health and Human Development (NICHD), USA that concluded that, direct and systematic phonologic awareness and phonics instruction produced significant effects in dyslexic children as well as children in kindergarten or first grade who are found to be at risk for reading disability.

Children identified as dyslexic receive systematic and highly structured instructions in basic phonologic skills required for decoding and reading. Instructions are provided either individually or in small groups of 2:1 or 3:1. Along with knowledge of phonics, a rapid sight word vocabulary is also focused on, for development of efficient reading. Difficulties in handwriting and mathematics are tackled simultaneously with instructions in phonology. Drills, rehearsals, practice and repetitions are required to consolidate the learning.

### Role of School and Parents

The role of the school and parents is very crucial in the successful remediation of a child with learning difficulties. The school has to be actively involved in the entire process of identification, assessment and remediation. For individual phonics instruction, children may have to be pulled out of the regular classroom for part of the school hour. Children with milder problems may be taught in the regular classroom itself but a high degree of awareness, commitment and motivation not to mention specific training is required from the teacher. Children may also need to attend after school programs.

The management of dyslexia in students in secondary school is based on accommodation rather than remediation. Accommodations are alterations in the way tasks are presented that allow children with LDs to complete the same assignments as other students. Common accommodations are preferential seating of the child, providing extra time for completion of tests, tape-recorded lessons and allowing verbal responses and frequent breaks. Individual tutoring or small-group instruction may be required in mathematics and/or written language if these disorders are also present. LD students in higher classes also need specific tutoring in study skills, organization of notes, time and material, and specific memory strategies. Use of assistive technology such as calculators, spell checkers, word processors and computers helps in making the task easier and makes it possible for learning disabled students to achieve success.

Parent counseling, education and support is essential to develop a supportive home environment and a consistent home/school program. Support and understanding of the parents and the school of the child's problem is vital for successful remediation. Affected children may also need other interventions such as pharmacological treatment if there is an associated ADHD or other comorbid conditions, social skills training for deficits in social cognition and behavioral management.

Periodic monitoring and review is essential to make sure that interventions are taking place. Review of pharmacological treatment, side effects is also necessary in children on medications.

### Facilities Available for Children with Learning Disability

Children evaluated fully and diagnosed as learning disabled by a registered psychologist can avail of many facilities. The psychologist has to make the recommendations suitable for the child and these recommendations are then forwarded to the relevant board of education through the school. Many educational boards recognize the difficulties faced by these children and are sympathetic to their plight.

- Second language exemptions are provided for children with dyslexia
- Extra time for board examinations is available
- Provision of scribes for children with dysgraphia
- Use of calculators in the examinations for children with dyscalculia.

National Institute of Open Schooling (NIOS) formerly known as the National Open School (NOS) is an autonomous educational board established by the Ministry of Human Resource Development, Government of India. NIOS offers a wide selection

of vocational and nonvocational subjects, as per students' choice regarding combination of subjects, up to the predegree levels. Students registered with NOS are free to select their subjects of choice in any combination and are free to pursue their education at their own pace. Several schools in major cities offer this facility. This is one option for education that pediatricians have to be aware of to guide their patients and parents (*www.nos.org*).

### IN A NUTSHELL

1. Learning disabilities are lifelong disorders. The diagnosis of affected children should be before second grade for better outcome.
2. Children with consistent poor school performance should be evaluated for learning disorders. Behavioral problems related to the educational setting should also lead to a suspicion of learning disorders.
3. Inclusive education with personalized attention in a supportive school and home environment is the cornerstone of management of specific learning disability (SLD).
4. Milder cases can be managed in the regular classrooms with slight modifications and accommodations. The moderate and severe cases need smaller group instruction.
5. Awareness of the facilities available for such children is not very well known and should be propagated by schools, pediatricians and other professionals.
6. Problems related to vision and hearing need to be ruled out before a structured evaluation for LD is done.
7. Phonetic-based management is important during preschool and primary classes.

## Chapter 21.12

# Anorexia Nervosa and Bulimia

Koushik Sinha Deb, Rajesh Sagar

Eating disorders (EDs) are a group of behavioral conditions characterized by insufficient, excessive or peculiar patterns of food intake which leads to health impairment and psychological distress in sufferers. Anorexia nervosa (AN) and bulimia nervosa (BN) are the most important EDs that have received wide attention from clinicians and researchers. However, it was increasingly realized that most patients with EDs did not meet the full criteria of either AN or BN, but rather fell somewhere in between, with some features of both. Currently *eating disorder not otherwise specified (EDNOS)* remains the most common diagnosis of ED reported worldwide. The recently published Diagnostic and Statistical Manual of Mental Disorders-5 (DSM-5) and the upcoming International Classification of Diseases (ICD-11 to be released by 2017) therefore have made significant changes in the conceptualization of EDs, along with introduction of several new categories.

Eating disorders were previously often considered as a *Western disorder* of the affluent, driven by the social and cultural pressure for thinness and perception of beauty, and were labeled as a form of *culture-bound syndrome*. Over the last few decades, multiple reports of ED have been documented from eastern countries, most notable from Japan, Hong Kong and China reflecting the undeniable march of globalization and changing value systems in Asia. In India too, these disorders are being reported with increasing regularity from metropolitan cities, in tune with the changing definition of Indian beauty from buxom to petite.

The Composite International Diagnostic Interview (CIDI) and the Eating Disorder Examination-Questionnaire (EDE-Q) are most commonly used tools to generate ED diagnoses. The EDE-Q (Fairburn and Beglin, 1994) provides extensive information on multiple eating problems is often considered the method of choice for ED diagnosis and assessment. The Eating Attitudes Test (EAT: Garner and Garfinkel, 1979) is the most commonly used screening instrument for EDs.

## ANOREXIA NERVOSA

Anorexia nervosa is an ED where sufferers drastically reduce their total food intake or partake in severe physical exercise and other purging behaviors in their inexorable quest for progressive thinness. The term anorexia nervosa is derived from the Greek word *anorexia*, meaning loss of appetite, and the Latin word *nervosa*, implying of nervous origin; although true loss of appetite rarely occurs in AN. The syndrome is characterized by a morbid fear of fatness, resulting in significant self-induced starvation, despite the presence of a normal appetite. A disturbance of body image, characterized by the perception that one is distressingly large or of an abnormal body shape is also present.

## Epidemiology

Anorexia commonly affects young females between the ages of 10 years and 30 years. The lifetime prevalence of AN in young females is around 0.9%, although it varies widely (0.1–5.7%) between individual studies. AN is 10–20 times more common in females than in males and is even more frequent in specific risk groups like fashion models, ballet dancers, gymnasts and those involved in wrestling sports. The prevalence of EDs in India is unknown although there has been a recent increase in case reports from Delhi and Bengaluru. A case finding survey in 2012 among 66 qualified psychiatrists in Bengaluru however found a surprising 74 cases of ED in the previous 1 year, including 32 cases of AN, 30 cases of EDNOS and 12 cases of BN.

## Etiology

Dysfunction in the neurotransmitters involved in regulating eating behavior; namely: serotonin, dopamine and norepinephrine are commonly reported in studies. Endogenous opioids may play a role in denial of hunger by anorexic patients and opiate antagonists like naltrexone have been shown to cause dramatic weight gains in some AN patients. The dopamine receptor D4 (DRD4) gene abnormalities were associated with the binge/purge subtype of AN. Starvation induced biochemical changes, such as hypercortisolemia, hypothyroidism, and positive dexamethasone suppression test are also seen, although they reverse on alimentation. Positron emission tomography (PET) studies report an increase in caudate nucleus metabolism. Family studies report a concordance rate of 55% in monozygotic twins as compared to only 5% in dizygotic twins, suggesting strong genetic loading. AN occurs in 4–5% of first degree relatives of probands, while occurring in less than 1% of controls. About 88% of the AN vulnerability can be attributed to additive genetic effects and 12% explain for individual environmental effects.

Psychological factors implicated in etiology of AN include having a lifetime of generalized anxiety and obsessive-compulsive traits, a lack of the sense of autonomy and selfhood, poor self-esteem and low optimism. Such temperamental traits when combined with precipitating factors such as teasing, stressful events, social comparison lead to precipitation of the disorder. The society's emphasis on thinness and exercise also reinforces anorexic belief systems in both gender. A gay orientation in men is proven risk factors as the need for muscular slimness are very strong in such groups. In contrast, a lesbian orientation may be protective in females, as female partners may be more tolerant and less demanding regarding weight and body shape.

## Clinical Features and Diagnosis

Anorexia nervosa patients eat significantly less, although they harbor a normal appetite and indeed are often excessively preoccupied with food. Various food fads like cutting food on plate in multiple small pieces rather than eating it, arranging food obsessively, and hiding food in bags or at home are often present in sufferers. Inability to maintain the anorexic control results in *binging*, characterized by sudden bouts of excessive eating, which is then followed by *purging*, commonly by self-induced vomiting. Other compensatory behaviors of AN include abuse of laxatives, diuretics, insulin, thyroid hormones or excessive jogging and strenuous exercising.

Due to the persistent and severe energy restriction, individuals with AN fail to maintain a body weight that is appropriate for age, sex and developmental trajectory. In severe cases, features of starvation like abnormal reproductive hormone functioning, amenorrhea, hypothermia, bradycardia, orthostasis, dependent edema, hypotension and lanugo hair appear. Adolescents with AN might suffer from delayed puberty, and adults generally also show an aversion to sex while anorexic. The diagnostic criteria for AN as per ICD-10 are described in **Box 1**.

Patients of AN often report additional obsessive-compulsive behavior, depression or anxiety symptoms. Major depressive disorder or dysthymia is the commonest comorbid diagnosis and may be present in up to 50% of patients with AN. About half of AN patients develop symptoms of bulimia sometimes during the illness.

## Differential Diagnosis

Medical illness that can account for the weight loss [e.g., a brain tumor, cancer cachexia, hyperthyroidism, human immunodeficiency virus (HIV), tuberculosis (TB) or other chronic wasting disorders] need to be ruled out in all cases. Of psychiatric disorders, depression may mimic AN, with loss of appetite and weight

**BOX 1 ICD-10 criteria for anorexia nervosa**

- Body weight is maintained at least 15% below that expected (either lost or never achieved), or Quetelet's body mass index is 17.5 or less. Prepubertal patients may show failure to make the expected weight gain during the period of growth
- A self-perception of being too fat, with an intrusive dread of fatness, which leads to a self-imposed low weight threshold
- The weight loss is self-induced by avoidance of *fattening foods*. One or more of the following may also be present: self-induced vomiting; self-induced purging; excessive exercise; use of appetite suppressants and/or diuretics
- A widespread endocrine disorder involving the hypothalamic-pituitary-gonadal axis is manifest in the female as amenorrhea and in the male as a loss of sexual interest and potency.

loss. Depressive patients however are lethargic and complain of tiredness, whereas AN patients often are overly active. Schizophrenic patients when aversive to food generally claim their food to be poisoned, rather than having calorific concern. Anxiety patients too may have decreased food intake and suffer from rapid weight loss, although they do not suffer from body image misperceptions. Multiple gastrointestinal and eating-related problems may occur in somatoform disorder but the focus on symptoms and recurrent treatment seeking differentiates them from AN patients who are generally secretive and try to avoid treatment.

### Management

These patients are generally brought to clinical attention unwillingly by their family members, often resist treatment, or are openly hostile to treating team. Therefore, involving family members into the treatment plan is necessary for success. Hospitalization, at least at the beginning of the therapy, may be needed for severe cases and in patients where compliance to outpatient treatment fails. The primary consideration during hospitalization is to correct patients' dehydration, electrolyte imbalances and nutritional state; as these can seriously compromise health or lead to death. Constipation often occurs in AN due to the minimal food intake and is usually relieved when patients begin to eat normally. Stool softeners may occasionally be given, but never laxatives. Realimentation should be started slowly because of the rare complication of stomach dilation and the possibility of circulatory overload when patients immediately start consuming large calories. Multiple small feeds (about six) throughout the day or liquid food supplement may be better accepted by patients.

Psychotherapy is preferred over pharmacotherapy. Cognitive and behavioral approaches have the most evidence base and include teaching patients to monitor their food intake, their bingeing and purging behaviors, and their problems in interpersonal relationships. Cognitive restructuring to identify automatic thoughts about body image and to challenge them are useful. Family therapy, stressing on family relationships may also help. In pharmacotherapy, selective serotonin reuptake inhibitors (SSRIs) have had some success in causing weight gain and in reducing symptoms anxiety or depression, and fluoxetine at dosage at or above 20 mg/day has shown some promise in preventing relapse. Of the antipsychotics, olanzapine may help reduce anxiety, agitation, and improve weight; particularly in patients with binge-purge subtype of AN. Cyproheptadine, amitriptyline, clomipramine and pimozide have also been tried with mixed success. Programs which combine pharmacotherapy with prominent behavioral therapy approaches show the best outcome.

### Course and Outcome

The course of AN varies greatly ranging from spontaneous recovery to a gradually deteriorating course resulting in death caused by

complications of starvation. Mortality ranges from 5% to 18%. Only 25% of patients improve completely from all symptoms with treatment. Binge eating-purging type patients show better recovery than restrictive subtype. Another half of patients improve partially, and continue to have some preoccupation about food and weight throughout life. Patients with childhood neuroticism, parental conflict, vomiting, laxative abuse and other comorbid psychiatric symptoms have the poorest outcome.

### BULIMIA NERVOSA

The term bulimia comes from Greek, meaning *ravenous hunger*, and is a disorder characterized by uncontrollable *food binges* and *food purges*. In contrast to AN, patients with BN generally maintain a normal body weight. BN can be considered as a failed attempt at AN, where despite their body weight concern, patients lack the superego strength to prevent their eating binges.

### Epidemiology

Bulimia is more common than anorexia, and the lifetime prevalence of BN is estimated to be around 2–4% in young women. In males, the rates of BN are less than in females, at around 1.5%. BN is ten times more common in women than in men, and has an onset in early adulthood, generally later than the onset of AN. During college years, about 20% of women of industrialized countries go through transient bulimic episodes, although most remit spontaneously. Prevalence of BN in India is not known although individual case reports are not uncommon.

### Etiology

The neurotransmitters related to satiety, serotonin and norepinephrine, are also associated with BN. Additionally, raised plasma endorphin levels in BN patients who vomit may explain the feeling of well-being which these patients experience after vomiting. Genetic predisposition is lesser than AN. Socially, patients of BN tend to be high achievers and respond to social and cultural pressures for slimness. These patients often suffer from other impulse control problems like alcohol abuse, shoplifting and self-destructive sexual relationships.

### Clinical Features

Bulimia nervosa is essentially characterized by three cardinal features: (1) binges, (2) purges and (3) body image disturbances.

*Binges* refer to periods of rapid consumption of food, accompanied by a sense of loss of control overeating. Food that is sweet, soft, high on calories and otherwise avoided; like cakes and pastries, are preferred. Stress, negative mood states, adverse comments about body shape and lapse in dieting regimes often precipitate them. Patients typically binge in secret, in the middle of the night, in bathroom or when otherwise alone. Food is gulped rapidly and often not even chewed and some patients will consume any food without consideration for taste. Generally, about 1,000–2,000 kcal of energy is consumed per binges, although *subjective binges* triggered by eating small quantities of food also happen in some. Abdominal bloating, pain, exhaustion or running out of stock generally ends the binges and patients often suffer immediate subsequent distress termed *postbinge anguish*.

*Purging* follows the binge to counter guilt, anguish and physical discomfort. The commonest purging method involves self-induced vomiting by inserting finger into the throat, although some patients vomit on will. At all other times, BN patients invariably follow a strict dieting pattern, where the type, quantity and time of eating are strictly predetermined.

*Body image disturbance* Bulimia patients suffer from a morbid fear of fatness, worry about their body image and harbor concern about their sexual attractiveness. These weight-related concerns are seen

in almost all EDs are therefore considered as *core symptoms*. In contrast to AN patients who are not interested in sex, BN patients are mostly sexually active. Bulimia patients also generally maintain body weight within the normal weight range, although some may be overweight or underweight.

Bulimia nervosa patients also suffer from high rates of comorbid mood disorders, impulse control disorders, substance-related disorders and a variety of personality disorders. Past history often reveals food fads, pica and sexual abuse in childhood. The diagnostic criteria for BN according to ICD-10 are provided in **Box 2**.

#### BOX 2 ICD-10 criteria for bulimia nervosa

- Recurrent episodes of overeating in which large amounts of food are consumed in short periods of time
- Additionally, persistent preoccupation with eating and a strong desire or a sense of compulsion to eat (craving)
- The patient attempts to counteract the fattening effects of food by one or more of the following: self-induced vomiting; self-induced purging; alternating periods of starvation; use of drugs like appetite suppressants, thyroid preparations
- Binge eating happens at least two times per week over a period of 3 months
- A self-perception of being too fat, with an intrusive dread of fatness
- There is often, but not always, a history of an earlier episode of anorexia nervosa, the interval between the two disorders ranging from a few months to several years.

### Differential Diagnosis

Differentiating BN from AN can be difficult at times as both the disorders share several core features and patients often have phases of AN and BN alternating during the course of ED. Most diagnostic guidelines give preference to the diagnosis of AN when symptoms of both are present and label the condition as AN binge-purge subtype. Only when body weight is maintained, the diagnosis of BN is made. Of other psychiatric disorders, while depression closely resembles AN, atypical depression mimics BN. Atypical depression, as the name suggests, is an atypical form of depression, where instead of lack of appetite, patients suffer from overeating and excessive sleep with prominent increased libido. Organic conditions that may resemble BN include the Klüver-Bucy syndrome and the Kleine-Levin syndrome. Klüver-Bucy syndrome, resulting from bilateral temporal lobe lesions, presents with hyperphagia and hypersexuality mimicking BN but is differentiated by additional presence of hyperorality, visual agnosia and docility. Kleine-Levin syndrome is a sleep disorder characterized by persistent episodic hypersomnia where patients may also experience hyperphagia and hypersexuality. Other conditions to keep in mind include temporal lobe epilepsy and central nervous system tumors.

### Management

In contrast to patients of AN, most patients of BN can be managed on outpatient department (OPD) basis and hospitalizations are rarely necessary, except for management of electrolyte imbalance or gastric/esophageal tears. BN patients are also less secretive as many consider the binges to be ego-dystonic (distressing) thereby actively partaking in therapy for decreasing binges.

Pharmacotherapy includes tricyclic antidepressants and SSRIs. Fluoxetine can reduce binge-purge episodes by 50%. A higher dose (60 mg) has been found better than 20 mg. Sertraline and fluvoxamine are alternative drugs.

Cognitive behavioral therapy (CBT) has shown robust evidence of effectiveness and many national guidelines (NICE: UK) now suggest it as a first-line therapy option with Level A clinical evidence base. CBT has more patient retention as compared to pharmacotherapy alone and the benefits of CBT are maintained

even 12 months post-therapy. CBT aims to modify patient's cognitive distortions about food, weight and body image; while behavior alteration focusses on interrupting the cycle of bingeing and dieting. Other psychotherapies which have shown promise in BN include interpersonal therapy and dynamic therapy.

### Course and Outcome

The outcome of BN is better as compared to AN, with 40–50% of treated patients showing complete remission. Untreated patients continue a chronic course with partial remission and exacerbations over the years. A longer duration of the illness at presentation, past history of AN, other comorbid disorders like depression and substance use predict poorer outcome. Patients who resist purging generally show better outcome.

#### IN A NUTSHELL

1. Around 2–10% of young women of western countries suffer from EDs. AN has a prevalence of 1% while BN has a prevalence of 2–4% in young women.
2. Eating Disorder Examination-Questionnaire is the most commonly used tools to generate ED diagnoses. The EAT is the most commonly used screening instrument for ED.
3. Disturbance in body image is considered as one of the core psychopathology of ED and is seen in most EDs. AN additionally has significantly low body weight while BN patients generally maintain body weight. Binges and purges may happen in both disorders.
4. Anorexia nervosa has significant genetic loading while bulimia has more environmental risk factors.
5. Treatment of both AN and BN includes psychotherapy (CBT) and pharmacotherapy. SSRIs, particularly fluoxetine has been found useful in treatment.

## Chapter 21.13

# Anxiety Disorders

Shoba Srinath, Preeti Kandasamy

Transient fear and anxiety occur in all typically developing children. Fear is an adaptive response with the severity falling on a continuum. Children typically manifest stranger and separation anxiety during infancy and toddlerhood, fear of darkness and animals in preschool and performance-related anxiety in school age which follows a developmental sequence and are usually nonimpairing. Anxiety is considered pathological when it is severe and persisting with extensive degree of avoidance, subjective distress and impairment.

## EPIDEMIOLOGY

Anxiety disorders are one of the most prevalent psychopathology in children and adolescent. Community surveys across the world have reported the prevalence of anxiety disorder ranging from 2% to 24%. In India, epidemiological studies have shown a prevalence of 4.1% among children aged 4–16 years and 14.4% among adolescents. In clinical samples, the prevalence is about 20%.

## ETIOPATHOGENESIS

Etiology is multifactorial with nature and nurture contributing to it. Twin studies have thrown light on the importance of nonshared environmental factors as concordance rates are often not more than 50%. While some of the anxiety disorders such as post-traumatic stress disorder are more influenced by environmental stressors; in most other subtypes, there is interplay between stress and vulnerability factors.

Family studies have shown a greater prevalence of panic disorder among family members of children with separation anxiety disorder. Research finding shows that what is inherited could be the vulnerability for a disorder than the disorder per se. Parental factors could contribute in two ways, one, through heritability others through modeling, fostering avoidance and/or through unhealthy parenting style such as overprotective, overcontrolling or overly critical parenting styles.

Behavioral inhibition, defined as the tendency to be unusually shy or to withdraw in novel situations, has been extensively studied as a risk factor for anxiety disorder; however, not all children develop impairing levels of anxiety as they grow up. Insecure attachment is also said to contribute to anxiety disorders.

Neurobiological research has shown serotonin, gamma-aminobutyric acid (GABA) and glutamate dysregulation and amygdala hypersensitivity in anxiety disorders. Of note is Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal Infections (PANDAS) which is characterized by acute onset of obsessive compulsive disorder and tic disorder.

## CLINICAL FEATURES

The presenting complaints are often not the classical anxiety symptoms. Children may present with school refusal, somatic complaints, dissociative (conversion) symptoms, poor academic performance, poor social interaction or tantrums and the anxiety symptoms become evident on eliciting the context of the above complaints. Developmental differences in presentation should be considered while evaluating a child for anxiety symptoms. Young children may not recognize fear as unreasonable, they may present with somatic complaints, crying, irritability and anger outbursts when faced by anxiety provoking situations.

Symptoms of anxiety can be cognitive, such as nervousness, fearfulness, self-defeating thoughts or difficulty concentrating; or behavioral which includes excessive shyness, avoidance, reluctance or restlessness; and/or autonomic disturbance most commonly sweating, tremulousness, hyperventilation, palpitation, etc.

## Subtypes

Separation anxiety and specific phobias are common in middle childhood; social phobia and panic disorder are more common in adolescence.

*Separation anxiety disorder* is characterized by developmentally inappropriate and excessive worry about separation from attachment figure associated with distress when anticipating or experiencing separation, worry about losing major attachment figure or experiencing negative event such as getting lost.

*Social anxiety disorder* is marked fear of social situations associated with fear of being negatively evaluated during peer interaction and not just in interaction with adults. Selective mutism can be considered a severe form of social anxiety where there is failure to talk in specific social situations, e.g., a child refuses to speak at school, but speaks well at home and the symptoms cannot be explained by a communication disorder or lack of knowledge of spoken language.

*Specific phobia* is marked by significant fear and avoidance of specific objects such as animals, natural environment, blood-injection-injury or situational.

*Generalized anxiety disorder* is manifested as excessive anxiety and worry about a number of events. It is characterized by free-floating anxiety and worries about past and future events not restricted to specific theme or situation.

*Panic disorder* is characterized by abrupt surge of intense fear associated with palpitation, trembling, sweating, shortness of breath, dryness of mouth with fear of dying or losing control.

*Obsessive compulsive disorder* though currently not classified under the rubric of anxiety disorders, is of considerable importance to a pediatrician as it has a prevalence of 1%. Children commonly present with repeated thoughts of contamination, harm befalling family members and repeated washing, checking, arranging compulsions and can be secretive about it. In post-traumatic stress disorder, children have recurrent intrusive memories of traumatic events, nightmares and avoidance of trauma-related cues.

## DIFFERENTIAL DIAGNOSIS

A good clinical evaluation can rule out any other medical cause for the anxiety symptoms such as hypoglycemia, hyperthyroidism, cardiac arrhythmias, mitral valve prolapse, pheochromocytoma, seizure disorder, migraine, medications or substance abuse/withdrawal that can cause autonomic disturbance mimicking anxiety symptoms. Anxiety symptoms are a common occurrence along with many psychiatric diagnosis especially depressive disorders. *Vice versa*, 28% to 69% of children with anxiety have a comorbid depressive disorder. Attention deficit hyperactivity disorder and autism spectrum disorder can also have co-occurring anxiety disorders.

## APPROACH TO DIAGNOSIS

Given the high prevalence of anxiety disorders in community and clinic sample, it would be good practice to routinely enquire for anxiety symptoms in children presenting with any behavioral or emotional problems. As anxiety has a protective function, drawing the line between normal and pathology can sometimes be a challenge. Key factors that a clinician should consider are the level of impairment in the form of interference with school or

social functioning, subjective distress and most importantly ability of the child to recover when removed from the anxiety provoking situation. These could indicate the severity of the symptoms and dictate management plans.

As it is primarily, a clinical diagnosis evaluation should include a detailed history of the onset, development and context of anxiety symptoms whether it is stimulus specific or spontaneous, anticipatory or generalized; assessment of school functioning and impairment, good family psychiatric history and treatment history.

Predisposing factors including temperament of the child, genetic vulnerability; precipitating factors such as bullying, change of school, exam; parental anxiety and unhealthy parenting style would help in understanding the child's symptoms. Maintaining factors such as parental responses or access to rewarding activities in child with school refusal need to be elicited and addressed.

Young children may have difficulties in communicating or elaborating the cognitive, emotional and behavioral symptoms; however, most children can label their emotion and the distress associated with it. Because of the subjective nature of anxiety symptoms, it is important to assess severity of anxiety and associated distress from the child or adolescent's viewpoint. Self-report screening questionnaire or clinician-rated scale such as Screen for Child Anxiety Related Emotional Disorders (SCARED) or Pediatric Anxiety Rating Scale can be used.

## MANAGEMENT

### Nonpharmacological Treatment

It is the mainstay of treatment (**Box 1**). Cognitive behavioral therapy is one of the most effective interventions. Some components which can be done in a pediatric set-up includes educating the child and parent about anxiety disorder and working in collaboration with them, explaining the mind-body relationship, thought-feeling-behavior cycle, teaching relaxation strategies such as diaphragmatic breathing, asking child to maintain tension diary to help the child monitor and make the stress symptom association. It is often useful to use a visual analog scale or *Tension* thermometer to help the child rate the subjective unit of distress at baseline and during follow-up.

#### BOX 1 Nonpharmacological interventions for anxiety disorders

##### Generic interventions for all anxiety disorders

- Relaxation strategies
- Monitoring anxiety on a visual analog scale (Tension diary)
- Problem-solving skills rather than avoidant-focused coping
- Positive self-talk

##### Specific interventions

- Systematic desensitization and exposure for specific phobia
- Graded return to school for separation anxiety, school phobia
- Graded exposure to feared social situations, social skills training, and role play for social anxiety disorder.

*Parental interventions* include addressing parental anxieties, helping parents encourage children to face anxiety provoking situations through graded exposure; use of gentle disciplining and avoiding criticism and intrusiveness; practicing relaxation and remaining calm when faced with an anxiety provoking situation to help the child learn through modeling. Sending a note to the teacher with the child's consent can help a child with school-related stressor.

### Pharmacological Intervention

Drugs are used as an adjunct in children with severe symptoms. Given that majority of the children show improvement with nonpharmacological interventions in a short span and considering

the long-term side effects with psychotropics, it is important to consider a trial of psychotherapy before deciding on medication when symptom severity is mild to moderate. Avoid short-acting benzodiazepine; when indicated a short trial (2–4 weeks) of long-acting benzodiazepine such as clonazepam 0.25–1 mg HS, with a tapering dosage schedule should be used with caution to avoid dependence. Sedative side effects can be a limiting factor. Children with prominent autonomic arousal in performance situations would benefit from beta-blockers such as propranolol 10–40 mg SOS if not contraindicated. In children with severe symptoms requiring long-term pharmacological interventions, selective serotonin reuptake inhibitors (SSRIs) are the first-line drugs. Most commonly used are low doses of fluoxetine, sertraline or escitalopram. Avoid tricyclic antidepressants in view of cardiac side effects. **Box 2** provides list of clinical situations where referral should be made.

## OUTCOME

Prospective studies have found that majority of children are free from their anxiety disorders at follow-up, with relapse only in a few children. However, adolescents with anxiety disorders are at an increased risk to develop depression, substance dependence and educational underachievement.

## PREVENTION

Primary prevention should focus on enhancing child's coping skills as it is a protective factor. Pediatrician can play an important role in early diagnosis as anxiety disorders are often under-reported and under-recognized.

### IN A NUTSHELL

1. Anxiety disorders cause significant impairment in academic and social functioning of children.
2. Parental anxiety and unhealthy parenting styles can be important predisposing factors.
3. These disorders have varied clinical presentation, indirect presentations are most common and presence of comorbidity is the rule.
4. Nonpharmacological interventions are effective. Pharmacological interventions to be offered only when symptoms are severe. When indicated, SSRIs are first-line drugs.
5. School-related stressor such as bullying and academic difficulties needs to be explored and addressed.

## Chapter 21.14

# Evaluation of Mental Well-Being

*Manju Mehta, Sneh Kapoor*

The role of sound mental health for healthy physical and emotional functioning is critical. Mental health is crucial in determining quality of life, relationships, vocation and productivity across the life span. It, then, becomes important to ascertain the role of mental well-being in the early formative years as a precedent to later development and functioning. Mental health problems in childhood cause difficulties not only for the child but also for the family and significant others. Thus, the understanding and adequate evaluation of mental well-being is important in childhood, and in some cases, starts right at infancy.

Evaluation of mental well-being of children often takes on a two-pronged approach. One may rely on a detailed clinical interview along with observation of the child in various settings, which are to be corroborated by reports of parents and teachers. Often, a clinician can also choose to use standardized scales to evaluate certain aspects of mental well-being such as cognitive development, social and adaptive functioning among others.

### DETAILED CLINICAL INTERVIEW: IDENTIFYING IMPORTANT SIGNS/SCREENING

A detailed clinical interview eliciting birth history, developmental milestones and any other significant medical conditions is the first step in evaluating the child for mental health issues. Following this, parents are asked questions pertaining to the child's present concerns or any concerns that the parents may have about the child's emotional or mental well-being, or any concerns regarding the child's behavior. Important signs to look out for *at home* could include sudden unexplained withdrawal from significant family members or some particular members of the family, excessive or age-inappropriate crying, aggression, sibling rivalry, excessive clinginess/withdrawal towards one parent/family member, excessive fear or avoidance of certain situations/places. Certain other complaints that the parents may come with may include incontinence/enuresis or age-inappropriate habits such as thumb sucking, nail biting. School-going children often report with complaints of frequent stomachache/headache/vomiting, or problems in adjusting to school life due to excessive social fear.

School-going children may report with the above concerns at home or may present with a different set of difficulties at school. Problems of sudden declining performance at school, loss of interest in class activities, withdrawal, poor participation, clinginess, school refusal/drop out or refusal to go home may be indicators of deeper rooted problems and could also be manifestations of childhood depression. Other problem behaviors or tell-tale signs could be inattention, hyperactivity, frequent out of seat behavior, irritability, aggression—both verbal and physical, bullying, etc.

### STANDARDIZED SCALES

Some important clinical scales that are often used in clinical practice to assess the mental well-being of children are discussed in this section. Some of the common scales are discussed below.

#### Development and Well-being Assessment

The Development and Well-Being Assessment (DAWBA) developed by Goodman et al. in 2000 is a set of interviews,

questionnaires and rating techniques that elicit information to help formulate a psychiatric diagnosis for children and adolescents between 5 years and 17 years of age. The diagnoses are based on the International Classification of Diseases, Tenth Revision (ICD-10) or the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) criteria and include common emotional, behavioral and hyperactivity disorders. Owing to its recent development, the test can be administered in both paper-pencil format, or by a computer for reduced cost and time taken.

#### Child Behavior Checklist and Youth Self-Report

The Child Behavior Checklist (CBCL) developed by Thomas Achenbach (2001) is a screening checklist devised to identify emotional and behavioral problems in children and adolescents. It is often used as a parent-rated or clinician-rated scale. The CBCL is for use with children/adolescents between 6 years and 12 years of age, and uses a Likert scale to assess for eight scales/syndromes. The Youth Self-Report (YSR), also developed by Achenbach, is a self-report screening tool for behavioral and emotional problems to be filled in by the concerned children or adolescents. It is standardized for use with children 11 years and older; and yields scores on eight empirically derived syndrome scales. These scales are listed below:

1. Anxious/depressed
2. Depressed
3. Somatic complaints
4. Social problems
5. Thought problems
6. Attention problems
7. Rule-breaking behavior
8. Aggressive behavior.

The 2001 revision also added six scales to screen for diagnostic categories according to the DSM:

1. Affective problems
2. Anxiety problems
3. Somatic problems
4. Attention deficit hyperactivity disorder (ADHD)
5. Oppositional defiant problems
6. Conduct problems.

The responses are to be rated in accordance with behavior over the past 6 months. The YSR and the CBCL are also scored on (optional) competence scales for activities, social relations, school and total competence.

#### Strengths and Difficulties Questionnaire

The Strengths and Difficulties Questionnaire (SDQ) is a brief behavioral screening questionnaire about 3–16 years old. It has various versions, all of which assess for 25 attributes, divided between five scales of: (1) emotional symptoms, (2) conduct problems, (3) hyperactivity/inattention, (4) peer relationship problems and (5) prosocial behavior (each with 5 items).

The same 25 items are included in questionnaires for completion by the parents or teachers of 4–16 years old (Goodman, 1997). For younger children (3–4 years old), a slightly modified informant version is used. Many clinicians use the SDQ as the initial self-report assessment before beginning the actual sessions or clinical assessment. These results can determine further assessments by guiding the clinician about other overlooked categories that may not have come up in the presenting problems. For example, a child that may be referred with complaints of oppositional behavior may also reflect on attentional problems on the SDQ, which may have been overlooked had the SDQ not been used during the initial assessment.

## Vineland Adaptive Behavior Scale

The Vineland Adaptive Behavior Scale (VABS) is designed to measure adaptive behavior of individuals from birth to age 90. The second revision of this scale contains five domains each with 2–3 subdomains. The domain scores yield an adaptive behavior composite. The main domains are:

- Communication
- Daily living skills
- Socialization
- Motor skills
- Maladaptive behavior (optional).

It is primarily used for measuring daily functioning and adaptive behavior and for screening purposes for diagnosis in the autism spectrum disorders or other genetic disorders. It can also be used as a screening for developmental delays or behavioral and emotional problems.

## Projective Testing

Tests such as *Draw-A-Person Test* as well as *Children's Apperception Test* are projective techniques. These tests are often employed for a deeper understanding of any conflicts or problems that the child may be facing that are not amenable to direct scrutiny or readily reported. Due to their ambiguous nature and the informal nature of activities involved (such as drawing, storytelling, etc.), these tests aid in rapport formation and are more accepted by children, who may feel daunted in a testing environment and may develop resistance to long scales and being repeatedly questioned about their behavior. In cases of deeper emotional problems and interpersonal conflicts, these tests yield valuable information that may not be reported directly on objective tests by parents or the children themselves.

## ASSESSMENT OF PSYCHOPATHOLOGY

Some commonly used clinical scales to assess common mental disorders that may occur during childhood, such as anxiety, depression, obsessive-compulsive disorder are enumerated in **Table 1**.

### IN A NUTSHELL

1. Early evaluation and identification is the key to facilitating promotion of mental well-being in children, and is the key to fostering later development and adequate functioning.
2. Evaluation of mental well-being of children often takes on a two-pronged approach: detailed clinical interview along with observation of the child in various settings; or use standardized scales to evaluate certain aspects of mental well-being such as cognitive development, social and adaptive functioning among others.

## Chapter 21.15

# Management of Psychological Illness

Paul Russell

Child psychiatric disorders can be broadly divided into those that have a developmental cause (e.g., autism), organic psychiatric illness secondary to disorders of the nervous system (e.g., trauma, infections) or other bodily systems (e.g., hypothyroid states resulting in depression), biologically mediated psychiatric illness where there are biochemical or electrophysiological abnormalities (e.g., psychoses and mood disorders) and psychologically mediated illnesses that happen because of psychological mechanisms of the mind that are maladaptive in nature (e.g., conversion disorder). This latter group of illnesses can be called as psychological illnesses.

Psychological illnesses (often described as having medically unexplained symptoms in primary care pediatric settings) are prevalent in 10% of children, with 11% among girls and 4% among boys. Recent research works support the view that childhood psychological illnesses have the propensity to continue into adulthood with significant impairment personally and illness burden to the society. This chapter will discuss the psychological illnesses in children with a psychological framework for its etiology and management.

### PATHOGENESIS

Though many biological models such as Hilgard's neodissociation model, Oakley's attention control model, Kozłowska developmental model, Stonnington's theory of mind model, and Brown's errors in information processing and representation model are all potentially plausible, the model that well explains the pathogenesis and has an effective treatment approach is the *psychodynamic model*. As these groups of disorders are psychological in nature and in order to understand the psychodynamic etiology with its consequent treatment techniques, the basic understanding of the human mind is essential.

### Understanding the Human Mind

The human mind is like an iceberg where the small visible tip, *the conscious*, is the first layer of the mind with all its contents fully available to our awareness (e.g., available to the memory). The *preconscious* is the second strata of the mind, of which the individual is mostly unaware, and has many psychological defense mechanisms that prevents re-entry of past life events and their associated unpleasant emotions (e.g., anxiety and sadness) from the unconscious to the conscious, and thus protects the child. Every traumatic life event, that is unpleasant to the child, is sent deep into the third level of the mind namely *the unconscious* that is totally unavailable to the child's awareness, by the primary defense mechanism of repression (Fig. 1). This defense mechanism of repression (mechanism by which events with their unpleasant emotions are kept away from consciousness) is effective enough to protect the child from emotional trauma most of the time.

### Response to Emotional Trauma

When the emotional trauma is overwhelming and the defense mechanism of repression is unable to repress the original traumatic event and the associated emotions into the unconscious

Figure 1 The structure and functioning of a normal mind

or, secondly, when similar traumatic events continue to happen, the original unresolved but repressed traumatic event gains more emotional strength and the trauma with its emotions escapes to the conscious, compounding the anxiety in the child. For this renewed traumatic emotions to be sent back to unconsciousness, other secondary defense mechanisms will have to be roped-in by the child's unconscious.

There are adaptive secondary defense mechanisms (e.g., humor, channelization, sublimation) and maladaptive secondary defense mechanisms (e.g., denial, regression, conversion). Depending on the type of secondary defense mechanism(s) used in addition to repression, the type of symptom presentation and thus the psychological illness varies. To explain this further, if the secondary defense mechanism of isolation (mechanism by which the life event and the emotions are isolated and thereby not interfering with the day to day thought process) and conversion (mechanism that converts isolated emotions into a physical symptom) are used after repression, the event is isolated from its emotions and the isolated emotions are converted into loss of bodily functions. Often the organ that perceived the traumatic event shows the bodily symptom, by the process of organ of choice, and specific organs are affected (e.g., child who had seen crime might become psychogenically blind). Similarly, isolation with dissociation (mechanism that splits a group of mental processes from the main body of consciousness) or isolation with somatization (mechanism by which thinking and feeling of bodily symptom is not differentiated) results in dissociative or somatoform/somatization disorders respectively.

In psychological illnesses, thus *primary gain* refers to the extent to which a bodily symptom diminishes the unpleasant emotions at the unconscious level (e.g., having a psychogenic seizure episode when the stern teacher at school reminds the student of the abusive father at home and the fight back at home between parents. Here the bodily symptom is produced unconsciously by psychological defense mechanisms, by which the child has diminished the overwhelming anxiety at that point in time. *Secondary gain* is achieved when the symptom presentation serves to help the individual avoid the situation generating the unpleasantness (e.g., having psychogenic seizures at home and thus can avoid meeting the stern teacher). Gaining attention, emotional support and tangible rewards with the aid of symptoms from persons in the environment are also examples of secondary gain. *Tertiary gain* refers to the homeostasis in the family that is brought about by the child's symptoms (e.g., parents not having fights and focusing on the child's symptoms that bring about peace at home). The treatment plan has to address all these forms of gains.

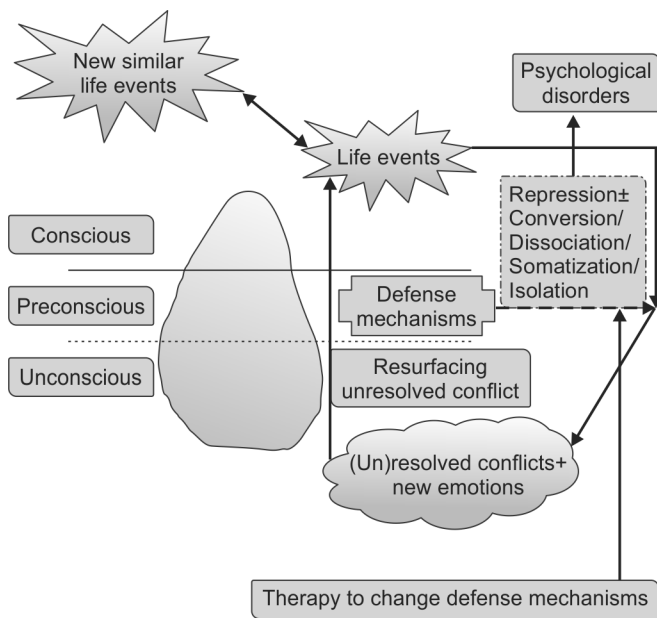

### PSYCHOLOGICAL ILLNESS

When the symptom is produced unconsciously (by psychological defense mechanism) for some unresolved unconscious conflict

(e.g., psychogenic seizures caused by unconscious psychological mechanisms to diminish the unpleasant emotions caused by factors the child is unable to identify), it is either a somatization/conversion/dissociative disorder (**Fig. 2**). The Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5) categorizes the psychological illnesses under the categories of dissociative disorder as well as somatic symptom disorder and related disorders, whereas the International Classification of Diseases (ICD-10) classifies these illnesses mainly under neurotic, stress-related and somatoform disorders (**Table 1**).

## DIAGNOSIS

These illnesses are generally of acute onset but can also have symptoms that may gradually worsen over time. In general,

**Figure 2** The mechanism of unresolved conflicts and defense mechanisms resulting in psychological disorders

**Table 1** The nomenclature of psychological illnesses in DSM and ICD diagnostic systems and their symptom presentation

DSM-5 illnesses	ICD-10 illnesses	Symptom presentation
Dissociative disorder	Dissociative/Conversion disorder	Dissociative identity Dissociative amnesia Depersonalization Derealization Trance and possession + symptoms of conversion for ICD-10
Somatic symptom disorder	Somatization disorder Somatoform pain disorder	Somatic symptoms with excessive symptom preoccupation and impairment
Illness anxiety disorder	Hypochondriacal disorder	Various somatic symptoms with excessive fear about an underlying illness and impairment
Conversion disorder		Paralysis Abnormal movement Swallowing symptoms Speech symptoms Seizures Sensory and special sensory impairments

psychological illnesses should not be considered as a diagnosis of exclusion although every somatic symptom in a pediatric setting should be investigated for a potential underlying physical illness. It should be remembered that psychological illnesses often concurrently exist with several medical and psychiatric conditions. Thus, initial diagnosis of psychological illness without a complete physical examination and other medical investigations is discouraged.

The diagnosis of any psychological illness has two components. Firstly, ruling out a physical cause and, secondly, ruling in a psychological cause for the somatic symptoms. If both these components are not considered together during diagnosis, the possibility of misdiagnosis and missed diagnosis will prevail especially in primary care pediatric settings, where medical diagnostic tests are less developed, and physical causes are not ruled out adequately. On the other hand, in tertiary care settings, overinvestigation for physical symptoms will happen and underdiagnosis of psychological illness can happen when psychological causes are not ruled out adequately. It should also be remembered that overinvestigation need not dispel fears but can exacerbate anxiety, as well as result in reinforcement and fixation of symptoms.

The treating pediatrician should request for medical investigations that keep with the symptom presentation and the potential organic diagnoses being entertained. Thus, laboratory investigations to exclude electrolyte disturbances, blood sugar disturbances, renal failure, systemic infection, toxins and medication, an electroencephalograph to distinguish pseudoseizures from a true seizure disorder; radioimaging to rule out an occult neoplasm or space occupying lesion may be required.

After ensuring the absence of a physical cause that can explain the presenting symptoms, the physician may use the DSM-5 diagnostic criteria for these disorders or, in busy settings, use appropriate measures for ruling in a psychological illness (e.g., Child Dissociative Checklist, Children's Somatization Inventory). Often, the psychological gains or stresses may not be apparent in the beginning, but they become evident later by their symbolic and temporal correlation to symptom onset or symptom worsening and symptom profile.

## DIFFERENTIAL DIAGNOSIS

The differential diagnoses for psychological illnesses range from life-threatening organic causes to normative behavior in children. Although there is a plethora of physical disorders that need to be considered as a differential diagnosis, which depends on the interpretation of the symptom clusters by the pediatrician, this chapter's focus is on illnesses that have medically unexplained symptoms.

### Normal Behavior

Developmentally, young children can present with physical symptoms without identifiable organic cause for a few hours or days after a minor injury. Cognitive difficulty in verbalizing the associated emotional distress is considered to be the cause for such physical symptoms. These symptoms are considered normal for children in this age group, and the role of psychological stressors is minimal.

### Symptom of Other Psychiatric Disorders

Physical symptoms can be part of many other psychiatric disorders like post-traumatic stress disorder, where peritraumatic conversion or dissociation symptoms are common. In these children, there is usually a historical evidence for catastrophic trauma (e.g., natural or man-made disasters that the child has witnessed or has

survived) in the past 6 months. Also, somatization, conversion or dissociation symptoms are often seen in anxiety disorders and depressive disorders among children. These disorders will have to be ruled out before the treatment plan is made.

### Factitious Disorder

The diagnosis of factitious disorder depends on evaluating two different dimensions in the child namely: (1) the awareness of the symptom production and (2) type of gains for the symptoms (**Fig. 3**). When the child voluntarily produces symptoms for some unresolved internal conflict (e.g., feigning bleeding for stresses caused by factors that the child is unable to identify, and often has to be uncovered with psychological tests), it is factitious illnesses. There is compelling need to produce symptoms for unknown psychological reasons, thus children with factitious illness can subject themselves through even invasive medical procedures and voluntarily hospitalizations.

### Malingering

If the child is voluntarily producing the symptoms for an identifiable and tangible external gain (e.g., feigning fits to avoid examination at school), it is malingering (**Fig. 3**). Inconsistencies between history and objective findings, as well as observations that are inconsistent should bring in the possibility of malingering or the Munchausen's syndrome among children with unexplained medical symptoms. Furthermore, in children, Munchausen by Proxy is also prevalent when a family member or caregiver can induce physical or psychological symptoms in the child for their own psychological benefits.

	External gain	Internal gain
Conscious symptoms	Malingering	Factitious
Unconscious symptoms	--	Somatization Conversion Dissociation

**Figure 3** Differential diagnosis for psychological illnesses

## TREATMENT

Children with psychological illnesses almost always present to the pediatrician or family physician as their first medical consultation because the presenting symptom is mostly medical in nature. Therefore, treatment from the prehospital to follow-up period of children, with medically unexplained symptoms, may change from a possible physical illness to a psychological illness.

### Prehospital Treatment

Treat patients as if their symptoms have a physical (developmental, neurochemical, neurophysiological or organic) origin as prehospital services (e.g., ambulance and triaging services) most often do not have the resources to distinguish a psychological illness from a physical illness.

## Hospital Treatment

### Rule Out Medical Cause

Pediatricians in emergency settings must be aware that the diagnosis of a possible psychological illness disorder does not eliminate the presence of underlying physical disease, and in acute care settings approach each child as if their symptoms have an organic basis and treat them accordingly. But again it should be reiterated here that the psychological illness diagnosis should not be made solely on the basis of negative medical reports.

### Arrange for Consultation

Consultation should be considered during the period of admission or discharge from casualty with other medical and surgical departments for any child with the first episodes of psychological illnesses. Organizing a psychiatric consultation is necessary when a physical cause is eliminated in the casualty or afterwards. Arranging for a psychiatric consultation minimizes the stigma and hospitalization by directing these patients to appropriate outpatient follow-up care in psychiatry. Despite the symptom genesis being in the mind, do not query the reality of the symptoms but acknowledge impairment and impacting of the symptoms on the child and family respectively. Before referring to psychiatry try to comprehend the family's viewpoint about the illness, level of certainty for physical causes, agreement with investigations, level of conviction for psychological causes and views about the psychiatric referral and treatment.

### Control of Dangerous Symptoms

Besides, if the child has symptoms that are dangerous to self or others in the surrounding a sedative, antianxiety agent can be administered. Usually a short-acting benzodiazepine that dissolves in the mouth (e.g., lorazepam 0.5–1 mg as a stat dose) can be given along with suggestion, in an authoritative and yet a not confrontative manner, that symptoms are likely to abate soon. Suggestions such as these will calm the child down in acute care settings but is not an end by itself for the psychological treatments.

### Outpatient Therapy

If the pediatrician or the family care physician decides to treat the child, instead of referring to a mental health professional, the following steps need to be followed.

### Face-Saving Measures

The child might be given some face-saving measures whereby the symptoms are acknowledged and a way out of the symptoms is given (e.g., for child with paraplegic symptoms, a supportive walker is provided initially and slowly graded down to tripod stick, walking stick and walking without any support) as the psychotherapy progress. The treating pediatrician at this point should stop all oral and parenteral medication given as the treatment for the physical symptom (e.g., analgesics for pain symptoms). As face-saving measure bandages, ointment and various physical therapies can be suggested. These measures should be accompanied by the information to the child that all medical tests indicate normal bodily functions, and the lost abilities can be recovered or pains controlled.

### Shifting from Medical to Psychological Model of Illness

While arranging the consultation, it is important that the pediatrician discusses with the family about the psychological nature of the illness. Make families aware of the high prevalence of medically unexplained symptoms among children. Furthermore, do not express a sense of awkwardness when communicating the diagnosis of a psychological illness, as such expressions might worsen the stigma and treatment compliance.

It is important to introduce the psychological model of illness to them, as by now the parents have come to believe that there is a possible medical illness with their child. It is important for the family to understand that neither the cause nor the effect of the symptoms has physically damaged the child. Firstly, teach the family about the mind-body relationship and how mind controls the body (e.g., on seeing a snake, fear happens in the mind and it commands the body to react). Secondly, the bodily reaction can vary from person to person for the same emotion of fear (e.g., run away, call for help, killing the snake or having psychogenic seizure). Thirdly, that some of these reactions are culturally accepted and understood (adaptive reaction like running away) and others are not (maladaptive reaction like having a psychogenic seizure). Fourthly, while adaptive reactions are mediated by adaptive defense mechanisms, maladaptive reactions are mediated by maladaptive defense mechanisms (as discussed before in detail). So one of the main goals is to help the child use more adaptive mechanisms instead of maladaptive defense mechanisms for handling various life events.

### *Shifting from Malingering to Psychological Model of Illness*

Following this, parents almost always change from a medical model for the symptoms, but often fail to recognize the difference between the psychological model and malingering model for the past symptoms, and as a result punishment ensues to stop as well as prevent such symptoms adding to the child's woes. Parents have to learn the difference between the psychological and malingering model as discussed before (**Fig. 3**).

### *Addressing of Secondary Gains*

While addressing the gains, start with the removal of secondary gains. Take an inventory of people, situation and type of secondary gains the child is obtaining (e.g., family members, peers, teachers, neighbors at home, school, neighborhood and play ground in the form of making the child sit down, massaging, avoiding going to school or giving attention). After identifying the nature of the secondary gains, explain to the family or others that such secondary gains work as rewards for perpetuating the demonstration of physical symptoms and has to be stopped (e.g., if the parents out of fear of symptoms occurring on going to school, allow the child to stay at home, it provides the child the chance to avoid many other possible unpleasant situations at school, not only the stern teacher, and thus acts as a secondary gain). Educate the parents that rewards like attention and tangible rewards should be contingent only on the child going to school without getting symptomatic and no reward is given whenever the child becomes symptomatic. When the child becomes symptomatic, it is best to ignore the symptom (and not the child as we are only against the symptom and not the child!): the most difficult step for the parent to follow, especially when the symptoms are so worrisome. Finally, also prepare the family to anticipate worsening of the symptoms when steps are taken to stop secondary gains, as children are not going to give up on symptoms that were so useful to them. If and when the worsening happens, instead of the parents getting worried, it helps them to reason out the cause for this aggravation in order to stay on course with your therapy.

### *Tertiary Gains*

When the physical symptoms in the child is the only way of keeping the family cohesive and the child understands his or her role in the family homeostasis (e.g., preventing divorce and thereby collapse of the family), the tertiary gains have to be addressed with marital and family therapies. As these therapies are time consuming and need a fair amount of professional training, an appropriate referral

to a mental health professional adept in addressing these concerns is needed. However, the pediatrician may have to look at the child rearing consensus among parents, enhance the limit setting roles of the parents, remove the role modeling of physical symptoms in the family, address power struggles among parents and siblings as well as improve verbal communication in the family that is making the child symptomatic. In some children, the primary and tertiary gain may be closely related and can be addressed together. Also, whenever indicated, group therapy is organized to learn relaxation, to build self-esteem, assertiveness and communication in the child.

### *Addressing the Primary Gains*

Discuss and guide the parents through understanding the maladaptive mechanisms (e.g., somatization, conversion and dissociation), the child is using and to help the child use more adaptive mechanism (e.g., channelization) for exhausting the isolated unpleasant emotions (e.g., channelize the emotions into doing something constructive). Teach the child to reframe his or her experiences in a positive light (e.g., a stern teacher need not remind him of his abusive father instead another similar person in the child's life, who is firm and yet the child is fond of). Also, sternness does not equate with abusiveness in two different persons' behavior. Help the child to get back to school and face the teacher in a graded manner (e.g., starting from seeing teacher's photographs, to watching his videos, to meeting the teacher in nonacademic settings, to sitting and enjoying his or her classes eventually!). Teach the child to change from emotional coping and use problem-solving coping (e.g., emotional or behavioral venting like crying or acting-out respectively relieves unpleasant emotions temporarily but does not solve the problem). Teach the child who might be crying, about the stern teacher, the multiple practical steps to get familiar with or even befriend the teacher!). Help children to identify and communicate emotional distress as such and not as physical symptoms. If there is suspected catastrophic traumatic events as a cause of psychological illnesses, trauma-related treatment is specifically warranted. Over time, an important goal of therapy is for the child to learn increasingly adaptive and flexible ways to manage their emotions and to integrate past, current, and new experiences so that physical symptoms need not arise due to psychological gains.

### *Follow-up Care*

If psychological illnesses in children can be identified early, it is relatively easy to treat and can prevent the development of more severe mental health problems. However, during follow-up as many as 83% of the children have been found to have other psychiatric disorders, while only 26.1% were still suffering from the psychological illnesses. In cases with comorbidity, pharmacologic interventions may be needed if concurrent depressive and anxiety disorders are identified. Hospitalization is indicated only if outpatient therapy is not effective, when life-threatening physical symptoms are noted or when removing the child from his or her environment is very essential for controlling the perpetuating symptoms (e.g., secondary gains) in disturbed family settings.

### *PREVENTION*

Children with recurrent somatic complaints should be identified by pediatricians, screened and provided simple coping strategies for their symptoms (e.g., distraction techniques). Secondly, teachers need to identify children with chronic school absenteeism because of physical symptoms and support them in developing problem-solving coping skills in situations they find difficult at school. These simple approaches can prevent symptoms reaching a disorder level with impairment.

### IN A NUTSHELL

1. Psychological illness, although not strictly a standard nomenclature terminology, describes different constellations of clinical presentations indicative of a child experiencing and communicating psychological distress through physical symptoms not explained by medical findings.
2. Despite the existence of many integrative pathogenic models to explain these disorders, psychological treatments that address the different types of gain remain the mainstay for treatment.
3. Medications play a role only if the child has life-threatening symptoms or if there is a concurrent psychiatric illness. Early identification and appropriate treatment of these illnesses result in better long-term outcomes.

# Section 22 NUTRITION AND NUTRITIONAL DISORDERS

Section Editors KE Elizabeth, Piyush Gupta

## Chapter 22.1

### Nutrient Groups and Nutritional Requirements

KE Elizabeth, S Bindusha

*Nutrition* is defined as the process by which the organism utilizes food. It signifies the dynamic process in which the food that is consumed is absorbed, metabolized and used for nourishing the body.

*Nutrients* are the chemical substances in the food that the body uses for functions that supports growth, tissue maintenance, and repair. There are six categories of nutrients: carbohydrates, protein, fats, vitamins, minerals, and water. Each category except water consists of a number of different substances. Nutrients which are not synthesized in the body or not synthesized adequately by the body are known as *essential nutrients*. They need to be provided by the diet and include carbohydrates, essential amino acids, essential fatty acids, vitamins, minerals, and water. *Nonessential nutrients* can be synthesized by the body (examples: glucose, cholesterol).

#### ENERGY

Energy requirement of an individual is defined as the level of energy intake from food that balances energy expenditure when the individual has a body size, composition, and level of physical activity, consistent with long-term good health, also allowing for maintenance of economically essential and socially desirable activity. In children, it includes the energy needs associated with the deposition of tissues at rates consistent with good health. Energy requirement must be assessed in terms of *energy expenditure* rather than in terms of energy intake. Energy intake may vary from day-to-day; on some days, it may be above the energy expenditure and sometimes, below it. Body energy reserves help to maintain normal energy expenditure over short periods even when the daily intake is below expenditure.

The energy expenditure consists of three components—basal energy expenditure, thermic effect of food and activity thermogenesis (**Fig. 1**). Basal energy expenditure (BEE) is the minimum energy expended that is compatible with life. Resting energy expenditure (REE) is the energy expended to maintain normal body functions and homeostasis. REE is 10–20% more than BEE. REE constitutes 60–70% of the total energy expenditure. Energy expended for growth is also part of REE. Growth requires 12–15% of total energy expenditure in infants. Thermic effect of food (TEF) is the increase in energy expenditure associated with consumption, digestion, and absorption of food. Thermic effect constitutes about 10% of total energy expenditure. Thermic effect varies from 5–30% depending on the composition of diet. A diet rich in protein has more thermic effect than a diet rich in fat. Spices, caffeine, capsaicin, and green tea increase the thermic effect of food. Activity

thermogenesis is the energy required for daily work, movement, and exercise. Energy expended for activity varies depending on the level of activity.

The traditional unit of energy is 1 kilocalorie (kcal/Cal). It is the amount of heat needed to raise the temperature of 1 kg of water by 1° Celsius from 14.5°C to 15.5°C. The international unit of energy is Joule. 1 calorie = 4.184 joule. 1 Joule = 0.239 calorie. Definitions of terms used for dietary reference intakes are listed in **Box 1**.

#### BOX 1 Definitions: Dietary Reference Intakes

##### Recommended Dietary Allowance (RDA)

The average daily dietary intake level of a nutrient that is sufficient to meet the nutrient requirement of nearly all healthy individuals in a particular life stage and gender group. RDA meets the needs of 97–98% of the population. RDA is usually fixed at 2 standard deviations above the average requirement. It is for the age in physiological state and not for the present weight of an individual.

##### Estimated Average Requirement (EAR)

The average daily nutrient intake level estimated to meet the requirement of half of the healthy individuals in a particular life stage and gender group. In infants it is the amount of the nutrient that results in maintenance of satisfactory rates of growth and development and/or prevention of specific nutritional deficiencies.

##### Adequate Intake (AI)

Recommended average daily intake level based on observed or experimentally determined approximations or estimates of nutrient intake by a group of apparently healthy people, which is assumed to be adequate—used when an RDA cannot be determined. In the Indian context, this is referred to as 'Acceptable Intake'.

##### Tolerable Upper Intake Level (UL)

The highest average daily nutrient intake level that is likely to pose no risk of adverse health effects for almost all individuals in the general population. As intake increases above the UL, the potential risk of adverse effects increases.

##### Dietary Reference Intakes (DRIs)

Dietary reference intakes include RDAs for those nutrients for which RDA is reliably established and other reference intakes where RDA is not established. These reference intakes include adequate intake (AI) and tolerable upper intake level (UL).

#### Energy Expenditure in Critically ill Children

Almost 16–20% of critically ill hospitalized children especially in those less than 2 years of age have been reported to develop severe acute malnutrition (SAM), following admission to a pediatric intensive care unit. Many children may also develop acute fluid and electrolyte malnutrition. The nutritional requirements and the nature of fuel utilization in critically ill children have not yet been defined. Overfeeding can lead to many side effects, including diet-induced thermogenesis, increased carbon dioxide production, and fatty deposition in the liver. Underfeeding, on the other hand, may result in depletion of fat and protein stores and malnutrition.

**Figure 1** Energy expenditure in health

Numerous equations have been used to estimate the caloric needs of the critically ill child. They calculate the predicted basal metabolic rate (PBMR) and then add the correction factor for the illness to calculate the predicted energy expenditure (PEE). Harris-Benedict and Food and Agriculture Organization/World Health Organization equation for PBMR is the most commonly employed (**Box 2**). The accuracy of the stress-related correction to PBMR in critically ill children is yet to be determined. There are various methods to calculate energy expenditure that include indirect calorimetry and bioelectrical impedance analysis. Another quick method is to give 2/3rd of the recommended dietary allowance (RDA) with 10% extra for the stress and the illness; the advantage is that it is easy and is not technology dependent.

#### **BOX 2** Equations for calculation of predicted basal metabolic rate (PBMR)

##### **Harris-Benedict equation (kcal/day)**

Males:  $66.473 + (13.7516 \times \text{Wt}) + (5.0033 \times \text{Ht}) - (6.755 \times \text{age})$

Females:  $66.50955 + (9.5634 \times \text{Wt}) + (1.8496 \times \text{Ht}) - (4.6756 \times \text{age})$

##### **WHO equation (kcal/day)**

3 years Boy:  $(60.9 \times \text{Wt}) - 54$

Girl:  $(61 \times \text{Wt}) - 51$

3–10 years Boy:  $(22.7 \times \text{Wt}) + 495$

Girl:  $(22.5 \times \text{Wt}) + 499$

10–18 years Boy:  $(17.5 \times \text{Wt}) + 651$

Girl:  $(12.2 \times \text{Wt}) + 746$

##### **Correction factors (% of PBMR added to PBMR)**

Elevated temperature + 12% per °C above 37°C (98.6°F)

ARDS +20%

Sepsis +10–30% depending on severity

Trauma +10–30% depending on severity

Surgery +10–30% depending on severity

## **CARBOHYDRATES**

Carbohydrates are the major source of energy. Carbohydrates consist of simple sugars (monosaccharide and disaccharide) and complex carbohydrates (polysaccharides, e.g., maltodextrin).

**Table 1** Glycemic index of common food items

Low glycemic index (55 or lower)	Medium glycemic index (56–69)	High glycemic index (70 or higher)
Apple	Sugar	Glucose
Orange	Brown rice	French bread
Mango	Chapathi	Baked potato
Banana	Sweet potato	Cake
Grapefruit	Cherry	Cornflakes
Milk		White rice
Milk chocolate		Watermelon
Carrot (raw)		Carrot (cooked)

Glucose, galactose and fructose are the common monosaccharides. Fructose is the sweetest sugar. Sucrose (2 glucose) and lactose (glucose + galactose) are the most common disaccharides. Invert sugar which contains unlinked glucose and fructose in a ratio of 1:1 is also available in nature. It is sweeter than sugar. Honey is an invert sugar. Starch, glycogen and fiber are examples of complex carbohydrates. Maltodextrin is a glucose polymer obtained by the partial hydrolysis of corn starch. Usually 45–65% of calories in food are from carbohydrates. Added sugar should constitute no more than 2.5% of total caloric intake.

Carbohydrates provide 4 calories per gram. Dietary fiber provides 2 calories per gram on an average even though humans cannot digest fiber. Fiber is converted to fatty acids by intestinal bacteria, which are absorbed from the intestine. The main function of fiber is to provide bulk to the food and prevent constipation. High fiber diet decreases the rate of glucose absorption and may prevent cardiovascular disease and colonic cancer.

**Glycemic index** It is the measure of the extent to which blood glucose is raised by 50 g portion of a carbohydrate containing food compared to 50 g of glucose or white bread. Food items are classified according to their glycemic index (**Table 1**). Food items with glycemic index 70 or above are classified as high, 56–69 as medium and 55 or less as low glycemic indexed food. Sugar, white bread, cake and baked or mashed potato are examples of food with high glycemic index. Grapes, tomato, apple, orange, carrot, banana, and apple are examples of food with low glycemic index. The method of cooking and processing also affects the glycemic index of the food.

## **PROTEIN**

The word protein means *of prime importance*. Proteins are needed for different biological functions. Proteins help in body building and tissue repair. They form enzymes, hormones, immunoglobulins and also help in transporting other nutrients. Proteins are made up of amino acids. There are 24 amino acids out of which 8 amino acids are essential for all ages. They are valine, leucine, isoleucine, lysine, tryptophan, methionine, threonine, and phenylalanine. Histidine is essential in infants. Arginine, cysteine, tyrosine, and taurine are also essential for low birthweight babies. The best quality protein should provide amino acids similar to the tissue protein. Breastmilk protein and egg protein are the best quality proteins. Egg protein is considered as the *reference protein* for the ease of making it available for laboratory references. The quality of protein depends on the extent to which the amino acid pattern resembles the reference protein. *Limiting amino acid* is the one found in lowest quantity in that protein compared to the reference protein. The overall quality of a specific protein can be increased by supplementing it with the limiting amino acid. The quality of soy

**Table 2** Protein quality of food items

Protein	Biological value	Net protein utilization	Protein efficiency ratio
Egg	96	96	3.8
Cow's milk	90	85	2.8
Meat	74	76	3.2
Fish	80	74	3.5
Rice	80	77	1.7
Wheat	66	61	1.3
Bengal gram	74	61	1.1

protein becomes equivalent to milk protein when supplemented with methionine, which is deficient in soya. Lysine is the limiting amino acid in cereals whereas methionine is the limiting amino acid in pulses. A cereal pulse combination provides a better quality protein than cereal or pulse alone. Measures of protein quality are summarized in **Box 3**. Protein quality of common food is summarized in **Table 2**.

**BOX 3** Measures of protein quality

*Digestibility coefficient* (DC) is the amount of absorbed nitrogen compared to the total nitrogen present in the food item.  $DC = \frac{\text{Absorbed nitrogen}}{\text{Total nitrogen}} \times 100$ .

*Biological value* (BV) is the amount of retained nitrogen compared to absorbed nitrogen.

$BV = \frac{\text{Retained nitrogen}}{\text{Absorbed nitrogen}} \times 100$ .

*Net protein utilization* (NPU) refers to the amount of retained nitrogen compared to the total nitrogen present in the food item.  $NPU = \frac{\text{Retained nitrogen}}{\text{Total nitrogen}} \times 100$ .

*Protein efficiency ratio* (PER) refers to the gain in weight of experimental animals per unit weight of protein consumed.

**FATS (LIPIDS)**

Fats are concentrated sources of energy. One gram of long chain fat provides 9 calories. Fats help in absorption of fat-soluble vitamins and are precursors of sex hormones and long chain polyunsaturated fatty acids (LCPs). Fats are categorized as *saturated* fats and *mono/poly unsaturated* fats (**Table 3**). Unsaturated fat contains double bonds between the carbon atoms in one or more of the fatty acids in it. If only one double bond is present it is monounsaturated fat, if more than one double bonds are present it is polyunsaturated fat. Saturated fats are stable and are solid in the room temperature. Animal fat in meat, butter and cheese, coconut oil and palm oil contain mainly saturated fats. Hydrogenation of vegetable oils will convert the unsaturated fats in them to saturated fats. Hydrogenation increases the storage life and baking quality of the oils. But saturated fat increases the blood level of low-density lipoprotein (LDL) cholesterol.

**Essential Fatty Acids**

The *essential fatty acids* are polyunsaturated fatty acids. They are linoleic acid and alpha linolenic acid. The essential fatty acids were previously designated as vitamin F. These essential fatty acids constitute a major component of the phospholipids of central nervous system. They are also needed for the production of prostaglandins and thromboxanes. Essential fatty acids are essential for normal fetal and infant growth, brain growth and visual acuity.

**Table 3** Fatty acid composition of oils

Oil	Saturated fatty acids (%)	Monounsaturated fatty acids (%)	Polyunsaturated fatty acids (%)	
			Omega 6	Omega 3
Coconut oil	92	6	1.6	0.4
Corn oil	13	25	61	1
Groundnut oil	18	49	33	0
Olive oil	14	77	8	1
Sunflower oil	11	20	69	0
Safflower oil	10	13	77	0
Palmolein	40	48	11	1
Hydrogenated vegetable oil	76	19	3	2

Linoleic acid is an omega-6 fatty acid. It is present in vegetable oils, meat and human milk. Alpha linolenic acid is an omega-3 fatty acid which is present in fish oil. Essential fatty acids are converted to long chain polyunsaturated fatty acids (LCPs). Arachidonic acid and adrenic acid are the derivatives of linoleic acids. These fatty acids are needed for production of prostaglandins and prostacyclins. Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are derivatives of linolenic acid (omega-3). DHA is found in large amounts in brain, retina and testes. Fish is a very good source of omega-3 fatty acids. Omega-6: omega-3 ratio of 5:1 or less is ideal for cardiovascular health. High omega-6 and low omega-3 content as in groundnut and sunflower oil, respectively can lead on to free radical injury, angiotoxicity, and impaired immune function.

Medium chain triglycerides (MCTs) are fatty acids containing 8–10 carbon atoms. They can be absorbed directly into the portal veins without the help of lipase or bile salts. Hence, MCTs will be absorbed even in conditions with fat malabsorption. Coconut oil and cotton seed oil are rich sources of MCTs.

There are two types of dietary fats—visible and invisible fat. Average indian diet provides 25–30% of calories as fats. The type of fat consumed is as important as the amount of fat consumed for healthy life. Not more than 10% of energy should be derived from saturated fatty acids. Approximately 10% should be obtained from monounsaturated fatty acids and 10% from polyunsaturated fatty acids. EFAs should provide 1–3% of the total calories.

**VITAMINS AND MINERALS**

Vitamins are chemical substances in the food that perform specific functions in the body. They are classified as *water soluble* and *fat soluble* vitamins. B complex vitamins and vitamin C are water soluble, whereas vitamin A, D, E and K are fat soluble. The stores of water-soluble vitamins are limited in our body. Exception is vitamin B<sub>12</sub>. Fat-soluble vitamins are stored in the fatty tissue and liver. These stores can last for months to years, even when the dietary intake is low. Excessive consumption of fat soluble vitamins especially A and D can lead to toxicity. Vitamin deficiency diseases and toxicity are discussed later in this section.

Minerals are classified into macrominerals and microminerals (**Fig. 2**). *Macrominerals* are elements present in higher concentration in the body. They constitute more than 0.01% of bodyweight. Calcium, phosphorous, sodium, potassium and magnesium are the major macrominerals. *Microminerals/trace elements* are elements present in concentration less than 0.01% of body weight. Trace elements essential for human growth and function include iron, iodine, zinc, copper, chromium, selenium, manganese, cobalt, molybdenum, nickel, vanadium, silicon, arsenic, fluorine and tin.

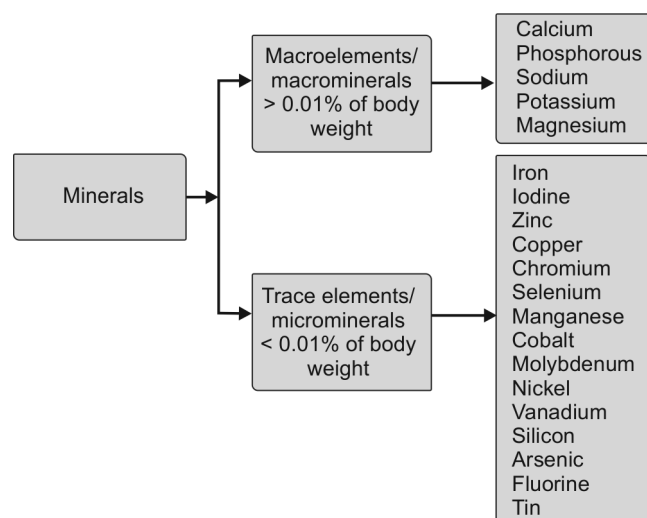

Figure 2 Minerals

Recommended dietary allowance of energy and major nutrients as recommended by Indian Council of Medical Research (2011) are summarized in **Table 4**.

### Calcium

Calcium is a major element in the body and is mainly present in the skeletal tissue. 99% of body calcium is present in the bone. Nonskeletal calcium has important functions like neuromuscular excitation, blood coagulation, and membrane permeability. Calcium is vital for body functions and hence the body tries to maintain calcium level even when there is dietary calcium deficiency. The calcium present in the bones has an important role in maintenance of serum calcium levels. Serum calcium level is maintained within normal limits by the interplay of vitamin D, parathyroid hormone, thyrocalcitonin, cortisol and sex hormones which control absorption and excretion of calcium and phosphorous and bone turnover.

Milk and milk products are the major sources of dietary calcium. When consumption of milk is low, cereals become the major dietary source of calcium. *Raggi, rajkeera* (amaranth), gingelly seeds, sea food, fish, mutton and green leafy vegetables are good sources of calcium. 20–25% of dietary calcium is absorbed. Vitamin D increases the intestinal absorption of calcium. Presence of phosphate in the milk and oxalates and phytates in the grains decrease calcium absorption. Calcium: phosphorous ratio of

2:1 is optimal for calcium absorption. Excessive intake of animal protein and sodium will increase the urinary loss of calcium. RDA of calcium for infants is 500 mg/day, 1–9 years–600 mg/day and 10–18 years is 800 mg/day. RDA for adult male and female is 600 mg/day which increases to 1,200 mg/day during pregnancy and lactation.

### Phosphorous

Phosphorous along with calcium is needed for the normal growth of bone and teeth. It is also a component of nucleic acid, phosphate esters, ATP, 2, 3-DPG and buffer systems. It is important in cellular metabolism, oxygen transport and acid base balance. Cereals, pulses, nuts and oil seeds are rich sources of phosphorous. 80% of phosphorous in the plant sources is present as phytate which is not absorbed. Phytate levels are low in polished rice and germinated seeds. All protein rich foods are rich in phosphate. Phosphorous deficiency can occur in low birth weight babies, children with malnutrition and those on parenteral nutrition. RDA of phosphorous for infants is 750 mg/day, 1–9 year–600 mg/day and 10–18 year is 800 mg/day.

### Sodium

Sodium is the principal action of extracellular fluid and is involved primarily in the maintenance of osmotic equilibrium and extracellular fluid volume. Sodium functions as the osmotic skeleton of the extracellular fluid. Maintenance of normal sodium levels are needed to maintain the normal size and shape of cells. The most common cause for hyponatremia is acute diarrheal disease. Hyponatremia can also occur due to excessive renal loss and excessive sweating. Salt is the major dietary source. Recommended intake of salt is less than 5 g/day. Requirement of sodium is 2–3 mEq/kg/day. RDA of sodium is 400 mg/day for infants, 600 mg/day for children between 1–3 years and 1,000 mg/day for children between 4 years and 6 years.

### Potassium

Potassium is the most abundant cation of intracellular fluid. Eighty percent of body potassium is in the skeletal muscles. Concentration of potassium in the extracellular fluid is around 4.5 mEq/L while the cells have about 150 mEq/L. Total body potassium content corresponds closely to lean body mass and nitrogen content. Potassium contributes to intracellular osmolality. Enzymes involved in glycolysis and oxidative phosphorylation are potassium dependent. It is involved in the maintenance of acid-base balance. Potassium deficiency and excess rarely occurs due to inadequate or excess intake. Deficiency of potassium occurs in

Table 4 Recommended dietary allowances of energy and nutrients

	Energy (kcal)	Protein (g)	Fat (g)	Calcium (mg)	Iron (mg)	Zinc (mg)
Infants 0–6 months	92 cal/kg	1.16/kg		500		
Infants 6–12 months	80 cal/kg	1.69/kg	19	600		
Children 1–3 years	1060	16.7	27	600	9	5
Children 4–6 years	1350	20.1	25	600	13	7
Children 7–9 years	1690	29.5	30	600	16	8
Boys 10–12 years	2190	39.9	35	800	21	9
Girls 10–12 years	2010	40.4	35	800	27	9
Boys 13–15 years	2750	54.3	45	800	32	11
Girls 13–15 years	2330	51.9	40	800	27	11
Boys 16–18 years	3020	61.5	50	800	28	12
Girls 16–18 years	2440	55.5	35	800	26	12

Source: Indian Council of Medical Research (ICMR); 2011.

diarrhea, malnutrition, diabetic ketoacidosis, and diuretic therapy. Hypokalemia produces skeletal muscle paralysis, abdominal distension and ileus.

Potassium is abundant in fruits and green vegetables. Cereals, pulses, nuts and oil seeds also contribute to significant amounts of potassium. Requirement is 2–3 mEq/kg/day. The ideal desirable sodium: potassium ratio in diet is 1:1.

## Magnesium

About 60–70% magnesium is present in bones, 25–30% in muscles, 6–8% in soft tissue and 1% in extracellular fluid. Magnesium forms complexes with phospholipids of cell membranes and nucleic acids. Magnesium is an important cofactor of the kinases, and is needed for the energy transfer reactions involving ATP and creatine phosphate. Magnesium is also important for maintaining electrical potential in nerves and muscle membranes. Magnesium deficiency leads to neuromuscular dysfunction. Serum magnesium is maintained in a narrow range like that of calcium. There is close association between calcium and magnesium. They have mutually reinforcing as well as opposing actions. Severe magnesium deficiency can lead to tetany and convulsions. Hypocalcemia and hypokalemia are always associated with magnesium deficiency and are reversed by magnesium repletion.

Plants form major source of magnesium. Magnesium is the metal in chlorophyll. Animal products, legumes and cereals are good sources of magnesium. About one-third of dietary magnesium is absorbed from the usual Indian diet. Dietary deficiency of magnesium will not occur unless associated with malabsorption syndromes or disease states like malnutrition. Requirement of magnesium is 3–6 mg/kg/day. RDA of magnesium is 30 mg for infants below 6 months and 45 mg for infants between 6 months and 12 months. Children between 1 year and 3 years will require 50 mg/day, 4–6 years: 70 mg/day; and 7–9 years: 100 mg/day. Adolescents will require an intake between 120 mg/day and 240 mg/day. RDA for adult male is 340 mg/day and female 310 mg/day.

## ANTIOXIDANTS

Free oxygen radicals and reactive oxygen species play a role in aging and various disease processes. Human body has an efficient system to protect itself from free radicals with antioxidants and enzyme systems. Antioxidants are substances whose presence in relatively low amounts significantly inhibits the rate of oxidation of targets. Vitamin E, beta carotene, vitamin C, phytochemicals like flavonoids, flavones, flavonols, cinnamic acid, coumarin derivatives, phytoalexin derivatives, trace elements like selenium, copper, zinc, magnesium and amino acids like cysteine and taurine are naturally occurring antioxidants.

Carotenoids consist of (a) provitamin A carotenoids like beta carotene; and (b) nonprovitamin A carotenoids like lycopene, lutein, canthaxanthin, and astaxanthin. All carotenoids are versatile antioxidants. Beta carotene acts by trapping free radicals produced during inflammation and is effective at low oxygen tension in the tissues. Carotenoids can also modulate the level of inflammatory mediators like prostaglandins and leukotrienes. Increased carotenoid levels have been associated with decreased LDL oxidation. Higher intake of food rich in carotenoids was found to reduce the occurrence of adult macular degeneration. Studies have also demonstrated a low incidence of coronary vascular diseases and cancers of prostate and breast.

Vitamin C can react with a wide range of reactive oxygen species, including superoxide, singlet oxygen and hypochlorite.

Vitamin C is a chain-breaking antioxidant and it protects lipids and membranes by scavenging peroxy and hydroxyl radicals. Vitamin C can also reduce heavy metal toxicity. Reduced glutathione reduces dehydroascorbate back to active vitamin C and vitamin C and glutathione are complementary to each other. A combination of vitamin C with vitamin E is more effective than vitamin C alone. Vitamin C and reduced glutathione acts on lipoic acid to regenerate vitamin E. Intake of vitamin C more than 500 mg/day has been found to reduce coronary vascular disease, hypertension, and cancers of oral cavity, esophagus, ovary, stomach and colon in adults.

Vitamin E is the primary chain-breaking antioxidant of lipids, lipoproteins, and membranes. Vitamin E acts as a peroxy radical scavenger, creating a tocopheryl radical. This radical will decompose unless converted back to tocopherol by reduced glutathione, vitamin C and coenzyme Q<sub>10</sub>. Vitamin E supplementation has been found to be associated with decreased incidence of atherosclerosis, Alzheimer's disease and overall cancer risk. Studies also suggest that vitamin E may act as a cell response modifier and improve cell mediated immunity. Vitamin E supplementation was also found to normalize serum IgE levels and heal the lesions of atopic dermatitis.

Flavonoids are one of the largest classes of polyphenols, and more than 4,000 different flavonoids have been identified. Their antioxidant properties, physiologic activities, and bioavailability vary according to major subclasses. Flavonoids can scavenge free radicals and block LDL oxidation. Flavonoids can also act as chelators and inhibit spontaneous generation of hydroxyl radicals.

Glutathione peroxidase is a selenium dependent enzyme which is a major antioxidant system. Selenium deficiency will lead to suboptimal level of glutathione peroxidase and hence oxidant injury. Copper, zinc, and manganese are indispensable metals for the activity of superoxide dismutase, which is the main oxygen scavenger in the body. Hence, dietary deficiencies of these minerals result in peroxidative damage and mitochondrial dysfunction. Deficiency of copper or zinc also enhances cytochrome P-450 activity in microsomes of liver and lung, and stimulates generation of reactive oxygen radicals.

### IN A NUTSHELL

1. Food supplies a variety of nutrients and energy that the body requires.
2. Optimum proportion and quality of items such as carbohydrate, protein, fat, vitamins and minerals are required for growth, survival and well being.
3. Intake of each food item should be guided by RDA, EAR, AI, tolerable UL, DRI to prevent excess and deficiency.
4. Diet should provide protective foods and antioxidants.
5. Energy expenditure in ill children varies from that of healthy children.

## Chapter 22.2

# Nutritive Values of Foods

Neetu Sharma, Piyush Gupta

## FOOD GROUPS

Indian Council of Medical Research (ICMR) in 2011 identified four main food groups in our diet. These are (a) cereals and pulses, (b) milk, egg and meat products, (c) vegetables and fruits, and (d) oils, fats, nuts and oilseeds based on their predominant nutrients (**Table 1**). To fulfill the nutritional requirement of the body it is important to include each group in daily diet, in the recommended proportion.

Food can also be categorized according to their functions:

- **Energy rich food** Carbohydrate rich foods like cereals, millets, sugar, starchy vegetables and the fat rich foods such as oil, ghee, butter, nuts and oilseeds are rich in calories. Intake of these foods is a must for physical activity and maintenance of overall health, growth, and recovery from illness.
- **Body building food** Protein rich foods, e.g., pulses, legumes, and nuts; milk and other dairy products, egg, meat, fish, belong to this group. This category is vital for growth spurt, maturation, and bone development.
- **Protective food** Protective food comprises of vitamin and mineral rich food sources such as fruits and vegetables, eggs, milk and milk products. Food material from this group is required to fight infections in children and prevent oxidative damage.

An in-depth learning about food groups allows us to comprehend the types of nutrients, and their impact on our body. This is vital not only in determining what constitutes a balanced diet, but also in assessing nutritional adequacy, as an aid for nutritional counseling, while briefing therapeutic diet to the patients and understanding food labeling.

## CEREALS

Cereals (e.g., wheat, rice, corn, oats and barley) form the major staple food in most parts of the world. They furnish generous amounts of energy and nutrients at low cost and have a significant position in the Indian dietaries. Rice and wheat are the most widely consumed cereals.

Cereals are an economical source of energy, mainly contributed by starch and fat, and a significant source of protein (6–12%), although of low biological value (incomplete protein). Cereals are better utilized when supplemented by the more complete proteins of milk, meat and eggs as they supply the amino acids lacking in cereals. Whole grain cereals are considerable sources of iron, phosphorous and thiamine. During milling of rice, the bran which is the outer layer of the kernel is discarded. Bran is rich in fiber and minerals. It is also a good source of thiamine and riboflavin. Polished rice thus obtained is lower in vitamins and minerals than parboiled rice. Parboiling is a process of hydrothermal treatment of paddy which drives nutrients, especially thiamine, from the bran into the grain, making it more nutritious.

Cereals are easily digestible, supply roughage and have a laxative property. Incorrect cooking practices lead to loss of water soluble vitamins, i.e., by cooking in large volume of water and draining away the excess of it. Nutritive value of some common cereals is presented in **Table 2**.

## PULSES

Pulses, alternatively called legumes, are the essential components of vegetarian diets due to their high protein content (20–40%). Proteins are needed for growth and repair of body tissues such as muscles, organs, skin, hair and blood. Except for *soybean*, pulse proteins are deficient in methionine and tryptophan. Groundnut and *soybean* are rich in oils. They are also good sources of Ca, Mg, Zn, Fe, K and P, and are fairly rich in niacin, but poor in riboflavin and contain small amounts of carotene.

Germination improves the nutritive value of pulses. The ascorbic acid, riboflavin, niacin, choline and biotin content increase considerably, and antinutritional factors (phytates, tannins) and toxic factors are eliminated. Fermentation increases digestibility, palatability and improves availability of essential amino acids. Such proteins can be of advantage in treating protein malnutrition as they are less expensive than animal proteins.

Some commonly consumed pulses are: green gram (*mung*), red gram (*tuvar/arhar*), black gram (*urd*), bengal gram (*chana*), lentil (*masur*), peas and soybean (**Table 3**).

## Vegetables

Vegetables vary widely in their composition and nutritive value, depending on the part of the plant which is used as a vegetable. Water is the major constituent of vegetables (about 99%). Vegetables contribute to the bulk of the diet and are low in calories, proteins and fats, though are rich sources of minerals and vitamins. Vegetables are of great use in weight reducing diets as they provide satiety due to bulk and contribute few calories. The bulk and water content also helps to relieve constipation.

Green leafy vegetables (GLV) such as spinach (*palak*), fenugreek (*methi*), *chaulai*, cabbage are good sources of iron, ascorbic acid, calcium and B-group vitamins. Some of these leafy vegetables contain oxalic acid which combines with calcium and forms an insoluble salt making it unavailable for absorption. However, GLV are essential, for the generous amounts of iron, ascorbic acid and vitamin A they provide in the diet.

Tuberous vegetables such as potato, sweet potato and yam (*garadu* or *ratalu*) are good sources of carbohydrates but are poor in proteins, vitamins and minerals. Carrots have rich amounts of beta-carotene (**Table 4**).

## Fruits

Fruits are valued for their minerals, vitamins and digestible fiber. Citrus fruits and guava are rich in ascorbic acid whereas yellow fruits contain carotenoids (precursors of vitamin A). Fiber content is more in fresh fruits than in fruit juices. Bananas provide calories in a nonresidue diet. They act as a mild laxative in constipation. Fruits are not good sources of calcium, phosphorous and iron. However, dried apricots, dates, grapefruit are fair sources of iron and calcium.

Apart from these micronutrients, vegetables and fruits are also rich sources of phytonutrients which act as natural antioxidants. Eating a wide variety of fruits and vegetables is recommended as a preventive measure against various free-radical mediated diseases (coronary artery disease, cancer, inflammatory bowel disease, etc.). A daily intake of at least 300 g of vegetables (green leafy vegetables: 50 g; other vegetables: 200 g; roots and tubers: 50 g) and in addition, fresh fruits (100 g) is recommended for an Indian adult. Nutritive values of some common fruits per 100 g of edible portion are given in **Table 5**.

**Table 1** Food grouping systems

Food group	Main nutrients
<b>Cereals, millets and pulses</b>	
<i>Cereals</i>	
Rice, wheat, ragi, <i>bajra</i> , maize, sorghum ( <i>Jowar</i> ), barley, riceflakes, wheat flour	Energy, protein, invisible fat, vitamin B <sub>1</sub> , vitamin B <sub>2</sub> , folic acid, iron, fiber
<i>Pulses</i>	
Bengal gram, blackgram, greengram, redgram, lentil (whole as well as dhals), peas, rajmah, soyabeans, beans, etc.	Energy, protein, invisible fat, vitamin B, vitamin B <sub>2</sub> , folic acid, calcium, iron, fiber
<b>Vegetables and fruits</b>	
<i>Green leafy vegetables</i>	
Amaranth, spinach, gogu, drumstick leaves, coriander leaves, mustard leaves, fenugreek leaves	Invisible fats, carotenoids, vitamin B <sub>2</sub> , folic acid, calcium, iron, fiber
<i>Other vegetables</i>	
Carrots, brinjal, lady's-fingers, capsicum, beans, onion, drumstick, cauliflower	Carotenoids, folic acid, calcium, fiber
<i>Fruits</i>	
Mango, guava, tomato	Carotenoids
Ripe, papaya, orange, sweet lime, watermelon	Vitamin C, fiber
<b>Milk and meat products</b>	
Milk, curd, skimmed milk cheese	Protein, fat vitamin B <sub>2</sub> , calcium
Meat, chicken, liver, fish,	Protein, fat, vitamin B <sub>2</sub>
Egg, meat	
<b>Oils, fats, nuts and oilseeds</b>	
<i>Fats</i>	
Butter, <i>ghee</i> , hydrogenated oils, cooking oils like groundnut, mustard, coconut	Energy, fat, essential fatty acids

## Milk and Milk Products

Milk and milk products are rich sources of calcium, protein and riboflavin, good sources of vitamin A, phosphorous, thiamine; and poor sources of iron and ascorbic acid (Table 6). The principal milk protein is casein, others

are lactalbumin and lactoglobulin. Milk is the only sources of vitamin B<sub>12</sub> for strict vegetarians and the only natural source of lactose. Milk from different sources varies in composition and nutritive value. The milk from one species is best suited for the needs of infants of that species only.

## Egg, Meat and Fish (Table 7)

### Egg

It consists of approximately 11% shell, 58% white and 31% yolk. Egg protein is considered to be one of the best proteins, as it has all the *essential amino acids* in adequate amounts. In egg protein is a standard or *reference protein*, against which quality of other proteins is assessed. Egg supplies generous amounts of both fat and water soluble vitamins. Vitamin C is present in small quantity. Calcium, phosphorous, iron, zinc are also present in egg. Iron and vitamin A are contained only in the yolk. Boiling/heating denatures *avidin*—a substance present in raw egg which binds biotin (B-complex vitamin) making it unavailable to the body. Egg is easily digestible and completely absorbed, hence, suited for convalescing patients. Since, it is low in fiber it is advised in patients with a gastrointestinal illness. Rich cholesterol content of yolk is avoided in obese or hypertensive children.

### Meat

Meats contain about 15–20% proteins of high nutritive value, with good amounts of essential amino acids. Fat content of meat varies between 5% and 40%. Organ meats (liver and kidney) are iron rich. Meat also provides zinc and B-vitamins. It is a poor source of calcium. Liver is a rich source of vitamin A. High meat diet is advised to patients with anemia and protein-energy malnutrition.

### Fish

It is an excellent source of proteins (16–20%) of good biological value, and of unsaturated fats especially omega-3 fats. Vitamin A and D are found in fish liver oils. B-vitamins and ascorbic acid present in raw fish are heat labile. Fish is also rich in calcium and phosphorous.

### Others

#### Fats and Oils

Fats provide fat-soluble vitamins and fatty acids essential for human nutrition, add palatability to the diet, and induce satiety. Certain elements/compounds in fat work as antioxidants and lessen blood cholesterol besides adding natural flavor like tocotrienols in palm oil, lignans in sesame oil and oryzanol and tocotrienols in rice-bran oil. The composition of minor elements gets modified if the oil is refined. Increase in blood lipid and thrombogenicity, and decrease in insulin sensitivity with risk of cardiovascular disease (CVD), obesity, stroke and cancer are associated with the saturated fatty acids. However, polyunsaturated fatty acids (PUFA), especially n-3 PUFA, are antiatherogenic, enhance insulin sensitivity and glucose utilization, and reduce adiposity. Appropriate functioning of nervous, immune, vascular and renal systems requires an adequate balance of the two categories of PUFAs, i.e., linoleic and linolenic acids in the diet. They are also vital for vision and

**Table 6** Nutritive value of milk (per 100 mL)

Name of foodstuff	Energy (kcal)	Protein (g)	Fat (g)	CHO (g)	Minerals (g)	Iron (mg)	Calcium (mg)

Mutton, muscle	194	18.5	13.3		1.3	2.5	150
Pork, muscle	114	18.7	4.4		1.0	2.2	30

Source: Nutritive values of Indian foods. National Institute of Nutrition, Indian Council of Medical Research;2012.

brain growth. An appropriate blend of saturated fatty acids (SFA), polyunsaturated fatty acids (PUFA) and monounsaturated fatty acids (MUFA) can be achieved by consuming more than one type of vegetable oils and eating foods rich in alpha-linolenic (ALA) acid such as legumes, green leafy vegetables, fenugreek and mustard seeds.

Fats are defined as *visible* and *invisible* fats. Visible fats refer to those that are used during cooking like ghee, vegetable oils, butter and *vanaspati*, whereas invisible ones are those that are found as integral components in various foods. The ones present in ready-to-eat and processed food are referred as *hidden fats*.

### Nuts and Oil Seeds

These are good sources of energy and contain good quality proteins in small amounts. Nuts contain appreciable amounts of carbohydrates, B-group vitamins and some minerals such as calcium, phosphorous and iron (**Table 8**). Oilseed proteins are of inferior quality as they lack methionine. But, being rich in lysine, they can be used to supplement cereals for development of weaning foods.

**Table 8** Nutritive value of nuts and oilseeds (per 100 g of edible portion)

Name of foodstuff	Energy (kcal)	Protein (g)	Fat (g)	CHO (g)	Crude fibers (g)	Minerals (g)	Iron (mg)	Calcium (mg)

### Sugar and Jaggery

They are used as sweetening agents. They contribute calories and palatability to the diet. Some amount of iron is also obtained from jaggery (**Table 9**). However, excessive amounts of sugar should be avoided as it might cause dental caries in small children. The most commonly used sugar is sucrose (table sugar).

### Condiments and Spices (Table 10)

These are used as flavoring substances and have an indispensable position in cooking, although they have limited nutritive value. Chilies and coriander (*dhania*) have little amounts of  $\beta$ -carotene. Most of them contain tannin which interferes with absorption of iron. Garlic is considered to have antibacterial property. Turmeric, ginger, garlic, cumin and cloves are rich in antioxidants. Excessive amounts of condiments should be avoided as they may lead to peptic ulcers.

### Beverages

Quenching thirst and providing body fluid is the main usage of beverages. Normal requirement of the body water varies with calories consumed. Water is required to regulate temperature and eliminate body wastes.

### Tea and Coffee

Tannin and caffeine, present in tea and coffee, provide stimulating effects, tea and coffee. Caffeine induces alertness, energy and overall sense of well-being. Higher intake of caffeine, over 200 mg can lead to anxiety, nervousness, higher blood pressure, arrhythmia, increased cholesterol and physiological dependence and can affect fetal growth. A cup of tea or coffee contains 50 mg and 100 mg caffeine roughly. Tea and coffee should not be taken 1 hour before and after meal because it interferes with iron and casein absorption. Tea also contains theophylline and theobromine, polyphenols and flavonoids which are associated with decrease risk of coronary heart disease and stomach cancer.

### Soft Beverages

There are two main categories of soft drinks, i.e., synthetic and natural drinks. Synthetic drinks are best avoided as they contain artificial colors, flavors and preservatives, and no nutrients. Carbonated beverages, as most of the synthetic drinks usually are, also affect appetite adversely and damage teeth enamel due to the phosphoric acid content. Natural drinks like fresh fruit juice, *lassi*, coconut water, and butter milk are healthier options. Butter milk and coconut water are ideal drinks as oral rehydration fluid. They should be avoided in hyperkalemia, acute adrenal insufficiency, and those with low urine output.

## FOOD PYRAMID

The food pyramid, a valuable roadmap for healthy diet planning, rests on the concept of energy density which combines nutritional values with portion sizes to cater to different needs or situations such as, the high energy density requirement in children and elderly people, or low energy density needs in case of obesity. Since no single food offers all essential nutrients in sufficient amount, a diet can be balanced only if it consists of food from all different food groups. Not all foods in a food group contain the same nutrients. So within each food group, the food selection should be assorted or diverse rather than a single one to fulfill the requirements of essential ingredients. Lastly, ensuring a proportionate intake of each selected food is as vital as is the assortment or balance itself. To sum up, a diet can be considered optimum only if it has a proper representation from different food groups in required proportions.

As illustrated in the **Figure 1**, in each of the food groups, a specific number of serving is recommended and healthy choices are emphasized. For example, in the *first layer of the pyramid* (at the bottom) are the cereals and milk, advised to be taken in adequate amount, as cereals/millet are used as staple food and are major sources of most nutrients, in this category, whole grains and emphasized; low-fat dairy products are encouraged.

Vegetables and fruits are at the *second layer of the pyramid* and unlimited amounts of fresh or frozen forms of each are recommended. Vegetables and fruits are rich sources of minerals, vitamins and phytonutrients. Fruits and vegetables are also rich in complex carbohydrates and fiber. Dietary fiber is important for proper bowel function, to reduce chronic constipation, and reduce plasma cholesterol. Some vegetables and fruits provide very low calories, whereas some others such as potato, sweet potato, tapioca and yam and banana are rich in starch which provides energy in good amount. Therefore, vegetables and fruits can be used to increase or decrease calories in our diet.

The *third layer of pyramid* about the use of protein and fat dictates that it should be used in moderation. The intake of

**Figure 1** Food pyramid

Source: Dietary Guidelines for Indians. 2<sup>nd</sup> ed. National Institute of Nutrition, Indian Council of Medical Research; 2011.

PUFA should be 8–10% of energy intake. Ideally a ratio of polyunsaturated/saturated (PUFA/SFA) of 0.8–1.0, and linoleic/ $\alpha$ -linolenic (n-6/n-3) of 5–10 is required. The intake of trans-fatty acids should not exceed 1% of energy intake. A combination of oils like soyabean, sesame, mustard, and sunflower should be used to achieve minor components in the diet. The use of *ghee*, butter, *vanaspati*, animal food, processed food should be minimized. Prefer fish over meat and poultry. Use of reheated oil and fat should be avoided. Ill effects of excess dietary fats are initiated early in life. Use of skimmed milk is advocated beyond 2 years of age. Consumption of fish, beans, and low-fat dairy products are encouraged from this layer. Increased amount of protein is needed for growing and ill children.

The *top (fourth) layer* consists of processed food and sugar that should be used as little as possible.

Food pyramid also offers the right combination of food intake to match with the physical activity. Daily physical activity, from lifestyle activities throughout the day as well as planned exercise, is an important component for weight management, especially of school children and adolescents. The ICMR food pyramid also cautions against intake of alcohol and tobacco.

### Balanced Diet

A diet can be termed as 'balanced' if it contains all nutrients in right quantity and required proportion offering diversity of belonging to the four basic good groups (**Table 11**). Though these quantities and proportions would differ as per age, physical activity, gender and physiological status, normally in a balanced diet, around 50–60% of total calories would come from carbohydrates, preferably complex carbohydrates, 20–30% from visible and invisible fats, and 10–15% from proteins. Besides, several nonnutrients like antioxidants, phytochemicals and dietary fiber should also be the parts of a balanced diet. While phytochemical like polyphenols, flavones save from oxidant damage, antioxidants like vitamin C and E, beta-carotene, riboflavin and selenium save from free radical damages. Some of the best sources of antioxidants in our everyday food are garlic, ginger, clove, cumin and turmeric.

**Table 11** Balanced diet for infants, children, adolescents (number of portions)

Food groups	g/portion	Infants (months)				Years					
		6–12	1–3	4–6	7–9	10–12		13–15		16–18	
						Girls	Boys	Girls	Boys	Girls	Boys
Cereals and millets	30	0.5	2	4	6	8	10	11	14	11	15
Pulses	30	0.25	1	1	2	2	2	2	2.5	2.5	3

Source: Dietary Guidelines for Indians. 2<sup>nd</sup> ed. National Institute of Nutrition, Indian Council of Medical Research; 2011

\*Quantity indicates top milk. For breastfed infants, 200 mL top milk is required. One portion of pulse may be exchanged with one portion (50 g) of egg/meat/chicken/fish. For infants introduce egg/meat/chicken/fish around 9 months.

## Recommended Dietary Allowance

The recommended dietary allowances are the quantities of nutrients that must be obtained from food to meet the physiological needs of healthy individuals according to their age and gender.

## DIETARY HABITS

With the passage of time, there has been a major change in the perception and discourse on dietary habits. Initially, this area used to be generally confined to the understanding and correction of nutritional deficiencies. Whereas lately, in the wake of constantly emerging evidences on diet pattern contributing to certain health risks, now it is considered to be a determinant of chronic diseases. This is all the more apparent in the astronomical increase in the lifestyle-related diseases due to the globalization and fast-paced lifestyle that have prompted people to opt for calorie rich, inexpensive, convenient-to-carry and ready-to-consume foods with long shelf-life containing excess salt, sugar and trans-fat, thus leading to harmful effect. Among the disorders that are on rise—obesity, cardiovascular diseases, hypertension, diabetes and certain types of cancers are of serious concern due to their increasing incidence in the younger age group. Hence, it is imperative that the awareness about healthy food culture is disseminated in the early phase of childhood for a healthy generation.

The dietary habits vary according to socioeconomic status, customs and traditions. **Box 1** offers a few tips for developing healthy dietary habits in childhood. **Table 12** depicts recommendations for a healthy lifestyle diet. This diet replaces the saturated fats with unsaturated fats which results in a decrease in the level of low-density lipoprotein (LDL) cholesterol and also emphasizes an increase in physical activity. In case of inadequate decrease in LDL, the amount of soluble fiber in the diet can be increased. The LDL-lowering power can also be enhanced by the food products that contain plant sterols.

## Cooking Methods

Cooking destroys harmful germs, makes food palatable and helps in digestion. Faulty cooking process and method can result in the loss of nutrients. Avoid repeated washing of food grains

prior to cooking, and do not reheat the leftover oil after deep-frying. Once cut, vegetables should neither be washed nor soaked in water for long. Cooking should be done in utensils with lid, and water should be used in adequate amount so that no excess

### BOX 1 Healthy dietary habits

- Exclusive breastfeeding should be provided till 6 months of age and it should be continued till two years or more.
- Complementary feeding should start with home based semisolid foods comprising cereal-pulse-nut and sugar/jaggery combinations that provide good quality protein, adequate calories and other protective nutrients, after 6 months. Energy density can be enhanced by using *Amylase-Rich Foods (ARFs)*. Details of ARFs are provided in the next Chapter.
- When a child starts learning to eat, they need help by parents. Many a times child push out food because they have not learn the skill of moving food inside or swallow solids. This is not a sign showing child is not interested in food. In fact, if food is regularly given to the baby, the ability to swallow develops automatically.
- Feeding is more successful when it is given in suitable feeding situation, i.e., all family members taking meal at same time so child develops interest in feeds, use separate bowl for the child, feed when child is alert and happy.
- Avoid food fads and discard erroneous food beliefs.
- During illness it is must to provide adequate and appropriate diets. Frequent small quantities, energy-rich cereals-pulse diet with milk and vegetables should be given to the child. Continue breastfeeding and give plenty of fluids during illness. Child should never be starved.
- Also assess whether foods prepared are safe or not. Talk to family to know whether following practices are fulfilled or not.
- Caregiver washes hands and utensils.
- Caregiver uses clean and safe water. In case, water is not deemed safe for drinking, one of the usual methods of purification is to boil it for around 10–15 min.
- Caregiver uses freshly prepared foods. If it is not consumed immediately, it should be stored either hot over 60°C or refrigerated below 10°C.
- Ensure good intake of polyunsaturated fatty acids (PUFA), whole grain cereals, vegetables and fruits in all age groups.

water is thrown away after the cooking. Cooking can be done by boiling, steaming, frying, roasting, baking and pressure cooking. While boiling leads to the loss of heat labile vitamins, microwave preserves nutrients but cooks unevenly. Processes of cooking that lead to loss of nutrients, such as deep frying, cooking at high temperatures, adding baking soda while cooking pulses, and cutting of vegetables in to small pieces, should be minimized. Nutritive value of the food can be enhanced by sprouting of grams, malting of cereals, and parboiling of grains. Prior to cooking, removal of pesticide residue from the food products is equally important and can be done by washing thoroughly in running water, blanching, and peeling.

### Processed Food

Restrict intake of preserved and processed foods like chips, salted biscuits, pickles, sauce, salted butter, and cheese. Processed foods

**Table 12** Therapeutic lifestyle change (TLC) diet

Diet component	Recommended intake
Total fat	25–35%
Saturated fat	< 7%
Monounsaturated fat	Up to 20%
Polyunsaturated fat	Up to 10%
Cholesterol	< 200 mg/day
Fiber	20–30 g/day
Protein	Approximately 15%

lack dietary fiber and micronutrients, and their frequent intake enhances the risk of exposure to various chemical additives and excessive intake of fat, salt, sugar and calories. Always read food labels for their nutrients and the additive presence and prefer fortified processed food.

Since people comprehend in terms of food intake rather than nutrients, it is constructive to explain in terms of food items and their quantity. Indian Council of Medical Research has provided approximate calorific value of some commonly cooked Indian preparations (**Table 13**).

### IN A NUTSHELL

1. Eat variety of foods to ensure a balanced diet.
2. Ensure provision of extra food and health-care to pregnant and lactating women.
3. Promote exclusive breastfeeding for 6 months and encourage breastfeeding till 2 years or as long as one can.
4. Feed home based semisolid foods to the infant after 6 months.
5. Ensure adequate and appropriate diets for children and adolescents, both in health and sickness.
6. Eat plenty of vegetables and fruits.
7. Ensure moderate use of edible oils and animal foods and very less use of *ghee*/butter/*vanaspati*.
8. Avoid overeating to prevent overweight and obesity.
9. Exercise regularly and be physically active to maintain ideal body weight.
10. Restrict salt intake to minimum.
11. Ensure the use of safe and clean foods.
12. Adopt right precooking processes and appropriate cooking methods.
13. Drink plenty of water and take beverages in moderation.
14. Minimize the use of processed foods rich in salt, sugar and fats.

## Chapter 22.3

# Infant and Young Child Feeding

JP Dadhich

Optimal nutrition during the first 2 years of life is important to lay down a strong foundation for growth and development of children. Recently, the focus has been drawn to the first 1,000 days of nutrition that include both intrauterine period (270 days of pregnancy) plus the first 2 years of life (730 days). The following infant and young child feeding practices, as recommended in the WHO/UNICEF global strategy for infant and young child feeding practices are imperative to achieve optimal growth, development and health.

- *Early initiation of breastfeeding* within one hour;
- *Exclusive breastfeeding* for the first 6 months of life;
- *Complementary feeding starting after 6 months* of life to meet their evolving nutritional requirements and to fill the nutritional gap between the total needs of the infant and the amount being provided by breastfeeding.

Infants should receive nutritionally adequate and safe complementary foods while breastfeeding continues for up to 2 years of age or beyond. Breastfeeding has been dealt with in the section on newborn care. Present chapter will mainly focus on the complementary feeding component of infant and young child feeding.

## COMPLEMENTARY FEEDING

Complementary feeding implies giving other foods in addition to breastmilk. These other foods are called complementary foods (WHO, 2004). National Nutrition Institute-Indian Council of Medical Research (NIN-ICMR) recommends home based semisolid foods to the infant after 6 months of age. Appropriate complementary feeding has been recognized as an important preventive strategy for child deaths, preventing 6% of child deaths. Improvement of complementary feeding through strategies such as counseling about nutrition in food secure populations and nutrition counseling, food supplements, conditional cash transfers, or a combination of these, in food-insecure populations could substantially reduce stunting and related burden of disease. Apart from being important to provide appropriate nutrients, introduction of diverse foods during infancy might have a protective effect on asthma, food allergy, and food sensitization with increased expression for regulatory T-cells marker.

## Status of Complementary Feeding in India

The proportion of children in India, who are fed with appropriate complementary feeding practices like timely initiation at 6 months consuming appropriate number of variety of food groups (i.e., three or more food groups for breastfed children and four or more food groups for nonbreastfed children); and minimum frequency of feeding (i.e., feed solid or semisolid food at least twice a day for infants of 6–8 months, 3 or more times for other breastfed children, and 4 or more times for nonbreastfed children) is depicted in the **Figure 1**. It is evident that in India, complementary foods is not introduced to 45% infants at appropriate time (6–8 months), minimum dietary diversity is available to only 12% children between 6 months and 23 months, and 56% are not fed with minimum frequency required. Coupled with the fact that more than half of infants are not exclusively breastfed during first 6 months, sub-optimal complementary feeding contributes significantly to child undernutrition in India.

**Figure 1** Complementary feeding indicators for India

Source: NHFS-3, 2005-06.

## Attributes of Complementary Feeding

Attributes of appropriate complementary foods include (a) timely start; (b) adequate in amount, variety and frequency; and (c) properly fed and safe.

### Timely Start

Breastmilk is sufficient to promote growth and development till 6 months of age. Complementary foods should be introduced after 6 months of age along with continued breastfeeding when need for energy and nutrients exceeds that is provided by breastmilk (**Fig. 2**). Also, around this age, infant's development and behavior makes him/her ready for foods other than breastmilk. Gradually, infant's tendency to push solids out decreases; infant starts showing interest in other people eating and reach for food; holds objects and like to put things in his/her mouth; starts moving the food around the mouth with better control of tongue and starts chewing the food. Also, the digestive systems are mature enough to begin to digest a range of foods.

Adding complementary foods before 6 months of age may decrease the intake of breastmilk resulting in a low nutrient diet and increase the risk of illness especially diarrhea. Likewise, adding complementary foods too late may lead to suboptimal growth and development and risk of nutritional deficiencies and malnutrition.

**Figure 2** Energy gap to be filled by complementary foods after 6 months of age

Reproduced with permission: From *Infant and young child feeding: model chapter for textbooks for medical students and allied health professionals*. WHO;2009.

### Adequate in All Food Groups

Complementary foods should be adequate in amount, containing various food groups to provide sufficient energy, protein, and micronutrients with optimum frequency as required for the age. Complementary foods should not replace breastfeeding and should be provided in addition to breastfeeding. Sequencing of complementary feeding in relation to breastfeeding does not affect total energy intake. Three or more food groups for breastfed children and four or more food groups for nonbreastfed children from food groups as mentioned below:

**Staples** Each community has a staple food, which is the main food eaten. Examples include cereals (rice, wheat, maize, and millets), roots (potato) and pulses. Cereals are the main source of energy. Cereals are usually milled to flour which is used to make bread (*chapati*) or make porridge. Cereals also provide proteins but are not very good source of micronutrients, millets (bajra, ragi) being an exception. Cereals also contain phytates which may interfere in the absorption of iron, zinc and calcium. It becomes important to use cereals with other sources of protein (like pulses and oil seeds like groundnuts) and micronutrients (like vegetables and fruits). Pulses and oil seeds contains fats, hence are a source of energy. Pulses with low fat contents are bengal gram, green gram, kidney beans, etc. Pulses and oil seeds with high fat content are ground nut, soybean, sesame, etc. Pulses and oil seeds also contain phytates interfering absorption of micronutrients. Beans contain antinutrients interfering utilization of nutrients by the body. Antinutrients could be removed by soaking the beans and throwing away the water. A cereal pulse combination in the ratio 2:1 is recommended for infant feeding.

**Fats and sugars** Oils and fats are concentrated source of energy and may be added to complementary foods to increase energy density without much increase in the volume. Fats and oils are also a good source of vitamin A. Sugar and jaggery are also energy-rich and can be added to foods to increase the energy content.

**Foods of animal origin (milk, curd, eggs, meat, fish)** Foods of animal origin are rich source of good quality proteins. Flesh and organs of animals are good source of micronutrients like vitamin A, zinc and calcium. Animal liver is a rich source of iron, vitamin A and folates, while egg yolk is a good source of vitamin A.

**Vegetables and fruits** Addition of vegetables and fruits to child's diet enrich it by providing vitamin A, iron, vitamin C and zinc.

A balanced diet for infants and young children should include appropriate amounts of above mentioned food group, as given in the **Table 11** of previous chapter.

### Iron Gap

Full-term infants are born with adequate iron store and get some iron in breastmilk, thus do not require additional iron for first six months of life. After six months of life, breastmilk iron is grossly inadequate and most of iron demand needs to be met with complementary foods. This is important to provide iron rich foods to children during this period to fill iron gap. Iron rich foods include green leafy vegetables, legumes, dried fruits, meat, fish and poultry products. Bioavailability of iron from plant foods is not optimum, addition of fruits rich in vitamin C increases the absorption of iron from plant foods. It is important to note that with increasing age (6–24 months) requirement for iron decreases (**Fig. 3**).

### Texture, Frequency and Amount of Complementary Foods

Complementary foods should be of right consistency (**Fig. 4**); soft; prepared with easy to digest, inexpensive, locally available and culturally acceptable ingredients; and easy to prepare at home.

**Figure 3** Iron need and supply in infants and young children  
Reproduced with permission: From *Complementary feeding—family foods for breastfed children*. WHO; 2000.

**Figure 4** Consistency of complementary foods (6–8 months)  
Reproduced with permission: From *Complementary feeding—family foods for breastfed children*. WHO; 2000.

These foods should be energy dense with variety to provide all nutrient demands of a growing child. Complementary foods may be started after 6 months with small amounts of mashed and semi-solids (e.g., porridge); quantity is increased with age, maintaining frequent breastfeeding. Gradually, food consistency, amount and variety are increased with age. Infant can be fed with finger foods by 8–9 months of age and by 12 months, family foods can be eaten. Frequency of complementary feeding should also increase with age as outlined in **Tables 1** and **2**. Certain food items need to be avoided in infants and young children, e.g., tea and coffee (interfere with iron absorption), aerated beverages (no nutritional value), too much sugary drinks and fruit juices (cause decreased appetite for other nutritious foods and also may cause loose stools), and nuts (may cause choking).

### Continued Breastfeeding

It is crucial to continue breastfeeding till 2 years of age and beyond as breastmilk remains an important source for energy, proteins and micronutrients like vitamin A and vitamin C for infants and young children even in the second year of life. It plays an important role in preventing undernutrition and morbidities. It can provide about one-third of energy needs, half of protein and 75% of the vitamin A requirements of a child of this age (**Fig. 5**). Thus, breastmilk helps a child to get enough energy and high quality nutrients from breastfeeding during the second year of life.

**Table 1** Practical guidance on the quality, frequency and amount of food to offer children 6–23 months of age who are breastfed on demand

Age	Energy needed per day in addition to breastmilk	Texture	Frequency	Amount of food an average child will usually eat at each meal
6–8 months <sup>1</sup>	200 kcal	Start with thick porridge, well mashed foods Continue with mashed family foods	2–3 meals per day Depending on the child's appetite, 1–2 snacks may be offered	Start with 2–3 tablespoonful per feed, increase gradually to ½ of a 250 mL cup
9–11 months	300 kcal	Finely chopped or mashed foods, and foods that baby can pick up	3–4 meals per day Depending on the child's appetite, 1–2 snacks may be offered	½ of a 250 mL cup/bowl
12–23 months	550 kcal	Family foods, chopped or mashed if necessary	3–4 meals per day Depending on the child's appetite, 1–2 snacks may be offered	¾ of a 250 mL cup

<sup>1</sup>The age ranges should be interpreted as follows: a child 6–8 months is 6 months or older ( $\geq 180$  days) but is not yet 9 months old ( $< 270$  days).

Reproduced with permission. From *Infant and young child feeding: model chapter for textbooks for medical students and allied health professionals*. WHO;2009.

**Table 2** Age-wise complementary foods

Age	Type of supplement	Example of food to be given
7th–8th months	Semisolid	Ready to eat infant mixes, well blended porridge, <i>kheer</i> , well mashed lentil with a boiled vegetable, potato and spinach puree, blended rice <i>khichri</i> , vermicelli <i>khichri</i> , sweet dalia
9th–12th months	Semisolid - solid	Poha with curd, potato with curd, millet <i>khichri</i> , <i>upma</i> , <i>idli</i> , <i>moong dal</i> mixture
Above 1 year	Solid	<i>Roti</i> , <i>cheela</i> , <i>parantha</i> , <i>laddoo</i> , biscuits, rice, <i>dal</i> (family food)

Source: IBFAN Asia, Navdanya, IHES, BPNI (2009). Complementary foods for children and young children (recipe for the people by the people).

## Responsive Feeding

Responsive feeding means the reciprocity between child and caregiver (Black and Aboud, 2011). It is important to make feeding a pleasurable experience for the infant. It also helps in ensuring intake of adequate amount of variety of foods. Responsive feeding is a three-step process:

1. The child signals requests through motor actions, facial expressions, or vocalizations.
2. The caregiver recognizes the signals and responds promptly in a manner that is emotionally supportive, contingent on the signal, and developmentally appropriate.
3. The child experiences a predictable response to signals.

Responding to the child with smiles and eye contact; talking to the child while feeding; feeding the child slowly with patience increase food intake; experimenting with different food combinations, tastes, textures; minimizing distractions during meals are few practices which helps in achieving responsive feeding.

## Maintaining Safety of Food

Complementary foods should be hygienically prepared, stored and fed. This can be achieved by:

- Washing caregiver's and child's hands before preparing, handling and eating food
- Using clean water and raw materials to cook food
- *Storing foods safely* Keeping food covered and serving shortly after preparation

**Figure 5** Nutrition provided by breastmilk in second year of life and gaps to be filled by complementary foods

Reproduced with permission from infant and young child feeding counseling—a training course, the '4 in 1 course' (integrated course on breastfeeding, complementary feeding and infant feeding and HIV), Breastfeeding Promotion Network of India (BPNI), Delhi.

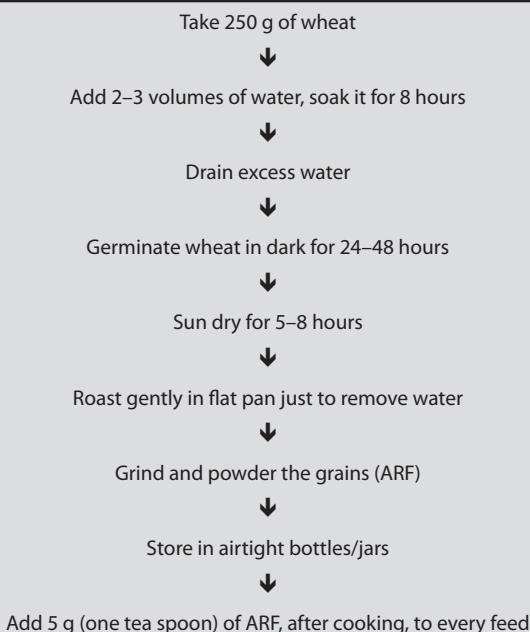

- Using clean utensils to prepare and serve food
- Using clean bowls and cups when feeding child.

## Amylase Rich Foods

Thick and viscous food prepared from cereals is difficult to swallow. Amylase (an enzyme) liquefies it and make easy to swallow without compromising the energy density. It increases acceptability of the food. Amylase rich food is prepared using the method shown in **Box 1**.

## Types of Complementary Foods

Complementary foods may be especially prepared foods, which may be either instant food mixes or freshly prepared foods or modified family foods. Instant infant food mixes may be prepared using roasted and powdered cereals, pulses, groundnuts, jaggery, etc. These mixes are stored in airtight containers and may be used for more than a month. Such foods are useful in families where frequent cooking in a day is not possible. Instant foods may be reconstituted for use by taking 4 tablespoon (about 50) of instant mix and 100 mL of boiled water, mixing thoroughly. Some oil/*ghee*, and sugar may be added to make it more palatable as well as to increase the calorie density. If available, some fruit/vegetable may also be added to it to make it more nutrient rich.

**BOX 1 Preparation of amylase rich food (ARF)****BOX 3 Recipes for fresh complementary foods****Suji Halwa**

*Ingredients:* Suji (roasted) 200 g, groundnut (roasted) 40 g, jaggery 100 g, Oil 10 mL, water 800 mL.

*Method of preparation:*

1. Grind groundnuts coarsely after removal of skin.
2. Heat oil in a pan, add *Suji* and fry till light brown.
3. Add groundnuts to *Suji* and mix well.
4. Add jaggery and water to the above and cook till it leaves sides.

*Nutritive values per 100 g:* Calories 408, protein 9.05 g, Iron 2.02 mg.

**Dalia Porridge**

*Ingredients:* Dalia (Broken wheat) 25 g, moong dal 20 g, milk 60 mL, sugar 30 g, ghee/oil 15 g.

*Method of preparation:*

1. Roast broken wheat in a pan.
2. When half-done add *dal* and continue roasting till light brown.
3. Add water to the above, cook till soft and slightly thick (semisolid).
4. Remove from fire. Add milk, sugar and oil. Boil for a few minutes and serve.

*Nutritive value per 100 g:* Calories 310, protein 6.5 g, Iron 1.5 mg, carotene 497 µg.

Two examples of such foods (adapted from a publication of FNB, Ministry of Women and Child Development, Government of India) are given in **Box 2**. Complementary foods can also be prepared fresh using commonly available food ingredients at home. These foods provide variety. Some examples of such foods are given in **Box 3**.

**Epilogue**

Along with breastfeeding, optimum complementary feeding with home prepared, age appropriate foods is crucial for ensuring optimum health and nutrition for the infants and young children.

**BOX 2 Recipes of instant food mix for complementary feeding****1. Wheat Food Mix**

*Ingredients:* Wheat 100 g, roasted bengal gram dal 30 g, groundnut 20 g, Sugar 50 g.

*Method of preparation:*

- Clean and roast wheat and groundnut separately (remove the outer skin of groundnut).
- Grind roasted Bengal gram dal and roasted groundnut and wheat separately to a fine powder. Mix all the ingredients thoroughly and add powdered sugar.
- Fill in dry airtight container and store.

*Nutritive value per 100 g:* Calories 386, protein 11.64 g, iron 3.75 mg, carotene 51.5 µg.

**2. Chidwa Mix**

*Ingredients:* Chidwa (rice flakes) 100 g, Bengal gram 30 g (roasted and de-husked), ground nut 20 g (roasted).

*Method of preparation:*

- Roast *Chidwa* and grind.
- Grind roasted groundnut (without skin) and Bengal gram separately.
- Mix all thoroughly. Store in a dry-airtight container.

*Nutritive value per 100 g:* Calories 381, protein 12.39 g, iron 15.63 mg, carotene 22.6 µg.

**IN A NUTSHELL**

1. Optimal nutrition during the first 2 years of life is important for growth and development of children.
2. Complementary feeding after 6 months of age along with continued breastfeeding is required to meet the evolving nutritional requirements and to fill the nutritional gap.
3. Appropriate complementary feeding is crucial in preventing undernutrition, disease and mortality in children.
4. Attributes of appropriate complementary foods include timely start; adequate in amount, variety and frequency; properly fed and safe.
5. Wholesome complementary foods may be prepared using ingredients available in the household.

## Chapter 22.4

# Feeding During Childhood and Food Allergy

KE Elizabeth, S Bindusha

Childhood and adolescence are periods of continuous growth and development. During the preadolescent period the child grows, on an average, 6–7 cm in height and 2–3 kg in weight every year and simultaneously development and maturation of various tissues and organs take place. So, they need more nutritious food in proportion to their weight than adults. Energy requirement of children depends on their basal metabolism, rate of growth, body size, age and activity. Enough calories should be provided for growth and to prevent protein being utilized for energy. Excessive calorie intake will lead to obesity. Children require adequate protein intake for growth and maintenance needs. Young children require around 1.8 g of protein per kg body weight, which decreases over years to 1.2 g/kg in late childhood. Proteins with high biological value should be included in their diet. Young children are at high-risk for iron deficiency due to rapid growth, increase in hemoglobin mass and increase in the total iron mass during growth. Lack of iron rich food in the diet adds on to this. Calcium is needed for adequate mineralization of growing bone. Milk and milk products are the major sources of calcium. Children who do not consume these are at risk of calcium deficiency. Vitamin D deficiency is also prevalent in our country, even though major part of our country lies near the equator. Dark pigmentation of skin, excessive clothing and lack of exposure to the sunlight especially during the peak hours are considered to be the causes. Zinc is essential for growth and zinc deficiency during childhood can lead to stunting.

## FOOD FOR PRESCHOOL AND SCHOOL CHILDREN

Young children between 1 year and 5 years should be given foods which are rich in energy and protein and low in bulk (example: legumes, pulses, nuts, edible oil or ghee, sugar, milk and eggs). Young children will consume more calories if small frequent feeds are given. The energy gap could be corrected by adding vegetable oil, ghee or sugar to the food. Food items which do not swell much on cooking like potato and banana are also energy dense. Vegetables including green leafy vegetables and locally available seasonal fruits should be part of their daily menu. Majority of children take more than three meals per day. Snacks make a useful contribution to the nutrient requirements, particularly in older children and adolescents. Snacks should be carefully chosen so that they are nutrient rich. Frequent changes in the menu are often liked by children. Older children and adolescents should consume plenty of milk to fulfill the high calcium requirements. Excessive salt intake should be avoided particularly by children having a family history of hypertension. School children should be encouraged not to miss breakfast and practice healthy eating using the food guide pyramid.

## FOOD FOR ADOLESCENTS

Adolescence is a period of rapid growth and is spread almost over a decade. This is a transitional stage in human development. It is characterized by rapid increase in height and weight, hormonal changes, sexual maturation and wide swings in emotion. Adolescent growth spurt starts at about 10–12 years in girls and 2 years later in boys. Development of critical bone mass is essential during this period as this forms the ground for maintaining mineral

integrity of the bone in later life. The pattern and proportion of various body components like body water, muscle mass, bone and fat increase during the entire childhood and adolescence to reach adult values by about 18 years. Adolescent girls are at greater physiological stress than boys because of menstruation. Their nutritional needs are of particular importance as they have to prepare for motherhood. All these rapid anabolic changes require more nutrients per unit body weight. The growth during this period is under the influence of nutrition, genetic and hormonal factors.

An adolescent boy is expected to consume 2,700–3,000 kcal/day, as equivalent to the requirement of an adult sedentary male. Adolescent girl requires 2,300–2,400 kcal, more than an adult sedentary female. Carbohydrates should make up 45–65% of energy intake; protein 10–30%; and fat 25–35%. Dietary fat should come primarily from sources of polyunsaturated and monounsaturated fatty acids, such as fish, nuts, and vegetable oils. Trans fats, found in hydrogenated oils used primarily in bakery products, should be avoided altogether because they increase serum levels of low density lipoprotein. Dietary intake of total cholesterol, found in animal products, should be limited to 300 mg/day.

Growing children and adolescents particularly require more calcium. Though recommended dietary allowances for calcium are about 800 mg/day only, it is desirable to give higher quantities of calcium for adolescents to achieve high peak bone mass. Adolescents are also at risk of vitamin D deficiency also due to inadequate exposure to sunlight. Adequate intake of iron should be ensured as iron is needed to build up the muscle mass and to prevent the development of anemia due to menstrual loss in girls. Malnutrition among adolescents may be due to various reasons other than unavailability of food. Many adolescents consume less food due to lack of time as they are engaged in a period of stressful studies. Breakfast is often missed or eaten hurriedly. Food fads and fast food culture also leads to malnutrition. Fast foods are high in calories, fat and sodium but fail to provide enough vitamins and minerals needed during this stage. Very little information is available about the nutrient composition of fast foods. Food additives like ajinomoto and coloring agents used for preparation of fast foods are antinutrients. Soft drinks also provide only empty calories. They may contain antinutrients. Consumption of soft drinks will kill the appetite and promote skipping of meals.

Peer pressure, media influence and rapid changes in the body size and shape may make them uncomfortable about their bodies. Some children especially girls eat less food as they want to remain slim. In some families, adolescent girls eat last and least due to ignorance and poverty. Psychological problems and eating disorders like anorexia nervosa and bulimia may also interfere with adequate nutrition. Adolescence is the period during which experimentation starts in all fields. Adolescence is the vulnerable stage for developing wrong food habits. Distinctive likes and dislikes for food may develop in this age. Developing unhealthy food habits may lead to nutrient deficiency. Dietary experimentation in the form of strict vegetarianism without proper knowledge about the healthy meal plans may also lead to malnutrition. In addition to consumption of a nutritious well balanced diet, appropriate lifestyle practices and involvement in physical activity such as games or sports should be encouraged among children and adolescents.

## FOOD ALLERGY

*Food allergy* is defined as an adverse health effect arising from a specific immune response that occurs reproducibly on exposure to a given food. The immune response may be IgE mediated, non-IgE mediated or a combination of both. *Food intolerance* is a nonimmune reaction that occurs after ingestion of food due to metabolic, toxic, pharmacologic or undefined mechanisms.

## Epidemiology

The prevalence of food allergy is increasing globally. Food allergy is more prevalent in the developed countries. Incidence of food allergy is 3–6% in children and 1–3% in adults. Children may outgrow their allergies over time. Food allergy that starts in adulthood often persists. Allergy to milk, egg, soy, or wheat is more likely to be outgrown than allergy to tree nuts or peanut. Resolution of a food allergy can occur as late as the teenage years.

## Pathogenesis

The major food allergens are egg, milk, peanut, tree nuts, fish, shellfish, wheat, and soy. Food allergens can cause symptoms when eaten either in the raw form or after being cooked. Cross reactivity can occur between different allergens which have structural similarity. Chemical additives in the food can produce adverse reactions which do not have immunological basis and hence considered as food intolerance.

IgE-mediated reactions are characterized by an acute onset of symptoms generally within 2 hours after ingestion of the trigger food. IgE-mediated reactions to foods typically involve the skin, gastrointestinal tract, and respiratory tract. Exposure to the allergen will stimulate the Th2 lymphocytes, which will stimulate the B-cells to differentiate into plasma cells and produce allergen specific IgE antibodies. Once IgE antibodies are formed they will bind to the tissue mast cells and basophils. Once the allergen specific antibodies have bound to the mast cells, the patient is considered as sensitized to that allergen. On re-exposure to the food, antigenic proteins in the food bind to and cross-link the IgE antibodies on the mast cells, which trigger the release of symptom-causing mediators, such as histamine and leukotrienes. Sensitization alone is not sufficient to define food allergy. An IgE-mediated food allergy requires both the presence of sensitization and the development of specific signs and symptoms on exposure to that food. Non-IgE-mediated immunologic reactions (e.g., cell mediated) include food protein induced enterocolitis, proctocolitis, and enteropathy syndromes. These conditions primarily affect infants or young children who present with abdominal complaints, such as vomiting, abdominal cramps, diarrhea, and occasionally blood in the stool and failure to thrive or poor weight gain. Examples of food allergy with mixed IgE- and non-IgE-mediated causes include eosinophilic esophagitis and atopic dermatitis.

## Clinical Features

Allergic reactions occur if the specific IgE is above a critical level. Symptoms of IgE-mediated food allergy can occur within minutes to hours of ingesting the trigger food and can vary in severity from mild to life-threatening. Severity of allergic reactions varies based on the amount of food ingested, preparation of the food and ingestion of other foods along with the trigger food. Severity can also be influenced by the patient's age, presence of comorbidities like asthma, as well as rapidity of absorption. The rate of absorption increases if the food was eaten on empty stomach or close to the time of exercise, leading to a more severe reaction. IgE-mediated reactions commonly affect the skin, gastrointestinal tract (Fig. 1), airways and rarely the circulatory system. Food induced anaphylaxis is a severe allergic reaction due to systemic release of mediators. It progresses rapidly and may possibly lead to death. Non-IgE mediated food allergy syndromes present predominantly with abdominal symptoms. Clinical features of various food allergy syndromes are summarized in Table 1.

## Diagnosis

Specific IgE can be demonstrated by positive allergic skin prick test or immunoassay of serum. These tests will identify foods that might provoke an IgE-mediated allergy. But they cannot be considered diagnostic of food allergy unless supported by history. Double-blind placebo-controlled food challenge (DBPCFC) is the most

**Figure 1** Cow milk protein allergy: endoscopic changes  
Source: Dr Rimjhim Shrivastava, Pediatric Gastroenterologist, Raipur, Chhattisgarh.

specific test for diagnosing food allergy. It can reliably differentiate between sensitization and allergy. Single blind or open food challenges may also be done in young children. A food challenge is indicated if specific IgE test results do not correspond to the history or if a screening test result for specific IgE is positive and the food was not introduced into the patient's diet till then. Diagnostic algorithm for food allergy is depicted in Flow chart 1.

## Treatment

The safest treatment for food allergy is strict avoidance of the causal food or foods. This holds good for all food allergy syndromes irrespective of the mechanism of allergy. Indiscriminate use of elimination diets without firm diagnosis should be discouraged, as it will lead to malnutrition. Once the offending antigen is found out that alone needs to be avoided. Patients should be educated on how to read ingredient labels on the food items to avoid their allergens. In many western countries, food-labeling laws require food manufacturers to declare in plain language on the food packaging whether one of the common allergens or a product derived from them is used as an ingredient. Similar laws are not in place in our country, and care is required to identify hidden forms of allergens.

Drug therapy depends on the symptoms. If patient presents with anaphylaxis intramuscular injection of 1/1,000 solution of adrenaline 0.01 mL/kg may be lifesaving. Children who have experienced anaphylaxis, and whose allergens are not clearly identified should be prescribed preparations of adrenaline like epipen for use in emergencies. Hydrocortisone, H1 and H2 antihistamines are used for urticaria. Steroids are used for treatment of eosinophilic gastroenteritis.

## Prognosis

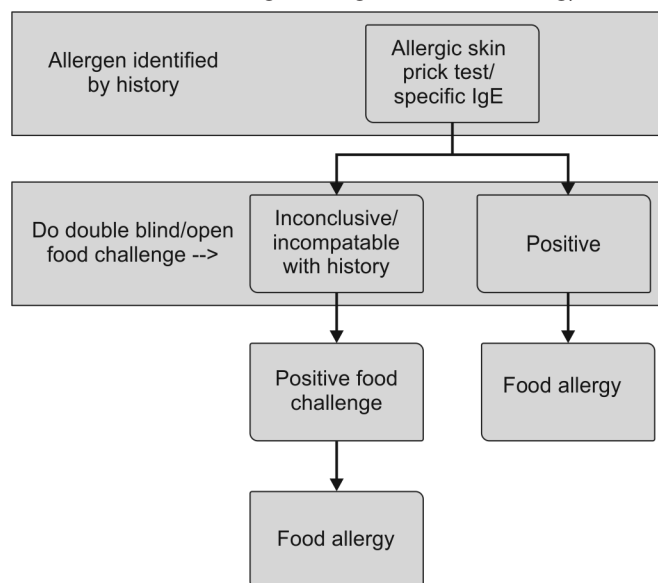

As age advances most children will be able to tolerate previously allergic food. Tolerance usually develops by 3 years of age. This is due to maturation of the gastrointestinal barrier system and development of immunological tolerance.

**Table 1** Food allergy: disorders, pathology, and clinical features

Disorder	Pathology	Clinical features	Food allergen
Urticaria/angioedema	IgE mediated	Common-acute urticaria	Milk, egg, peanut, tree nut, fish, shellfish, wheat and soy
Anaphylaxis	IgE mediated	Rapid progression, shock Multi organ involvement	Any, but commonly peanut, tree nut, fish, shellfish, milk and egg
Food-associated, exercise-induced anaphylaxis	IgE mediated	Food triggers anaphylaxis only if exercise follows ingestion	Wheat, shellfish and celery
Oral allergy syndrome (pollen-associated)	IgE mediated	Pruritus and mild edema in the oral cavity, rarely progress beyond mouth Anaphylaxis—very rare increase after pollen season	Raw fruit and vegetables birch pollen—apple, peach, pear and carrot ragweed—melons
Immediate gastrointestinal hypersensitivity	IgE mediated	Immediate vomiting, pain	Milk, egg, peanut, tree nut, fish, shellfish, wheat and soy
Atopic dermatitis	Combined IgE and cell mediated	Food allergy in 35% with moderate to severe rash	Major allergens, especially egg, milk
Eosinophilic esophagitis	Combined IgE and cell mediated	Gastroesophageal reflux, vomiting, dysphagia, food impaction	Multiple allergens
Eosinophilic gastroenteritis	Combined IgE and cell mediated	Ascites, weight loss, edema, obstruction	Multiple allergens
Food protein induced enterocolitis	Cell mediated	Usually in infants vomiting, diarrhea, poor growth, lethargy	Milk, soy, rice, oat, meat
Food protein induced allergic proctocolitis	Cell mediated	Usually in infants Mucus and blood in stools	Cow's milk—through breastfeeds
Heiner syndrome	Cell mediated	Pulmonary infiltrates, failure to thrive, iron deficiency anemia	Cow's milk

## IN A NUTSHELL

### Healthy Eating Practices

The following principles are recommended for the healthy eating campaign.

1. Moderation in all things. Ensure a balanced diet by including all food groups every day. Food pyramid will help in the choice of balanced diet. Include cereal pulse combination, roots and tubers in adequate quantities, vegetables and fruits liberally, milk, milk products and meat in moderation and oils, fats and sugars sparingly.
2. Variety is the spice of life. Ensure variety within each food group. Food fads must be avoided as it may evolve as a social handicap.
3. Knowledge about what is enough—adolescent boy should eat as much as his father eats and the adolescent girl should eat a little more than what the mother eats.
4. Some people claim that vegetarianism is healthier. This depends on the degree of vegetarianism. Vegetarians have low-risk of obesity, hypertension, coronary arterial disease and colon cancer. Vegans are at risk of calcium, iron and vitamin B<sub>12</sub> deficiency. Whole grains and germinated seeds are beneficial for them. Lacto-ovo-vegetarians have very little nutritional risk except iron deficiency due to lack of heme iron. Fruitarians who eat only fruits are at the risk of protein, sodium, calcium and other mineral deficiency.
5. Micronutrients and antioxidants including beta-carotene, vitamin A, vitamin C, folic acid, iron, iodine and zinc are essential for healthy life.

## Chapter 22.5

# Undernutrition: Prevalence and Etiology

Piyush Gupta, Neetu Sharma

Adequate food and nutrition are essential for proper growth and physical development, optimum work capacity, normal reproduction, adequate immunity, and resistance to infections. Inadequate diet may produce several forms of undernutrition in children, the most important being protein-energy malnutrition (PEM), and micronutrient malnutrition like nutritional iron deficiency anemia (IDA), vitamin A deficiency (VAD), and iodine deficiency disorders (IDD). Undernutrition can be categorized as macronutrient (protein, fat, and carbohydrates) and micronutrient (vitamins and minerals) deficiency.

### MACRONUTRIENT MALNUTRITION

Nutritional deficiency of macronutrients results in a syndrome of protein-energy malnutrition (PEM). *Severe acute malnutrition* (SAM), the most severe and life-threatening form of PEM, is often associated with infection; and contributes to high child mortality. Early onset of malnutrition can also have lasting effects on growth and long-term functional status. The magnitude of macronutrient malnutrition cannot be fathomed easily from the prevalence of *marasmus* and *Kwashiorkor* as they represent only the tip of the iceberg. Moderate and mild undernutrition may remain unrecognized because clinical criteria for their diagnosis are imprecise and difficult to interpret accurately.

### MICRONUTRIENT MALNUTRITION

Micronutrients deficiencies are termed as *hidden hunger*, as they do not give rise to apparent manifestations till the condition becomes severe. Micronutrient malnutrition continues to affect over 2000 million people worldwide. It is difficult to assess the true burden of micronutrient malnutrition as it requires laboratory facilities, advanced technology and other resources. There are several reasons for micronutrient deficiencies. The population

may be deficient because they have poor access to micronutrient rich food due to poverty, defective crop growing pattern, deficient soil quality, inappropriate climate, or geographical isolation. Traditional dietary fads may also hinder intake, absorption, or utilization of micronutrient rich foods. Cereal-pulse based Indian diets are qualitatively deficient in iron, calcium, vitamin A, riboflavin and folic acid, due to low intake of green leafy vegetables, fruits, and foods of animal origin. The food distribution within the family is also inequitable.

Micronutrient deficiency is clinically evident only in the later stages of the disease; manifesting with impaired work capacity, learning disability, increased susceptibility to infections, and greater risk of death. For the country, it translates into loss of economic productivity, and hike in investment on health and education. According to WHO, over 2 million child deaths (around 20% of total) are attributable to zinc, vitamin A, iron, and iodine deficiency. These micronutrients cannot be synthesized endogenously and have to be supplied in the diet.

### PROTEIN-ENERGY MALNUTRITION

#### Global Prevalence

More than one-fourth of under-five children worldwide (about 150 million) are underweight; 27% (182 million) are stunted, while 10% are wasted. Almost two-thirds of undernourished children live in Asia, 29% in Africa, and 3% in Latin America and the Caribbean. Despite an overall decline in the prevalence of stunting, child malnutrition still remains a major public health problem in developing countries (**Fig. 1**). In South Asia, every other child can be classified as underweight. **Figure 2** depicts the global prevalence of underweight in children below 5 years of age. It is now recognized that about 53% of all deaths in young children are attributable to underweight.

#### India

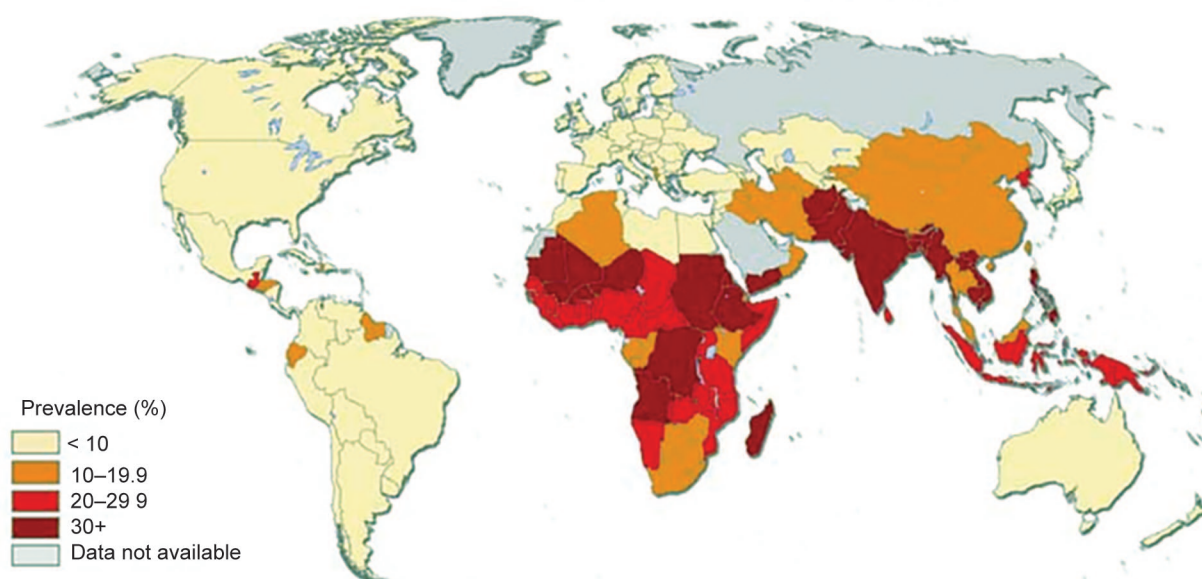

There has been a significant decline in the prevalence of severe protein energy malnutrition in India, over past few decades. The proportion of children under 3 years of age who were underweight decreased from 53% in National Family Health Survey (NFHS)-1 (1992-1993) to 47% in NFHS-2 (1998-1999), and 46% in NFHS-3 (2004-2005). Similarly, prevalence of stunting decreased from 52% in NFHS-1 to 45% in NFHS-2 and 38% in NFHS-3. According to NFHS-3 (2005-2006) survey report, 43% of children

**Figure 1** Prevalence of malnutrition in under-five children

Source: The State of the World's Children 2014. New York. The United Nations Children's Fund.

**Figure 2** Global prevalence of underweight in children under 5 years of age, 1995–2004  
Reproduced with Permission from Deonis M et al. WHO.

under five years of age were underweight, and almost half (48%) were stunted (**Fig. 3**). Wasting (weight for height  $< 80\%$  or  $< 2SD$  of expected) was less prevalent, affecting 20% of children under 5 years of age.

*Statewise situation* Malnutrition varies widely across region, states, age, gender and social groups, being worst in children under two, in the populous northern states, in rural areas, and among tribal populations and scheduled castes. The proportion of children under 5 years of age who are underweight ranged from 20% in Sikkim and Mizoram to more than 50% in Madhya Pradesh, Jharkhand and Bihar. Other states where more than 40% of children were underweight are Meghalaya, Chhattisgarh, Gujarat, Uttar Pradesh, and Odisha. The overall prevalence of underweight (46%

versus 33%), stunting (51% versus 40%), and wasting (21% versus 17%) are higher in rural settings, compared to the urban areas.

### Etiology

#### *Maternal Malnutrition and Lack of Breastfeeding*

In postnatal life also, these infants receive less attention from the mother who is overworked and weak. The nutritional status of children is also strongly related to maternal nutritional status. Undernutrition is more common for children of mothers whose body mass index is below 18.5 than for children whose mothers are not underweight. Malnourished mothers have a high incidence of low birthweight and growth retarded babies with poor nutritional reserve. These low birthweight babies are more likely to become

**Figure 3** Nutritional status of under-five children in India (NFHS-3)

malnourished. Lack of exclusive breastfeeding for first 6 months makes the child prone to early onset malnutrition. Artificial feeding is often disastrous for the baby because of the poor quality of the substitute milk, excessive dilution and use of unhygienic feeding bottles and nipples. High pressure advertising by baby food manufacturers and social demands on the urban educated working women has encouraged early discontinuation of breastfeeding. Unfortunately, evaporated dry milk powders and packaged foods are expensive. Poor mothers tend to economize on their use and offer diluted milk formula to the infant. Unhygienic feeding practices in the preparation of milk formula result in frequent episodes of diarrhea and diminished absorption of food by the infant.

### *Delayed Introduction of Complementary Feeding*

According to NFHS-3 data, only 56% of infants aged 6–9 months received complementary semisolid foods as recommended. In most rural households, introduction of semisolid foods is delayed, often beyond one year. Most of the times, it is the diluted animal milk in small quantities, which is used to supplement breastfeeds.

### *Infections*

Frequent infections contribute to undernutrition. Diarrhea, pneumonia, malaria, measles, whooping cough, and tuberculosis precipitate acute malnutrition and aggravate the existing nutritional deficit. During infections, child's appetite is impaired. There may be iatrogenic restriction of food by the parents. The body tissues are catabolized and metabolic demands are escalated. Protein may be lost because of tissue breakdown and in pus and exudates. Also, malnutrition may adversely affect the immune status and make the malnourished individuals more vulnerable to infections. This sets up a vicious cycle of malnutrition-infection-malnutrition.

### *Food Quality and Quantity*

Nonavailability of food, either due to poverty or inaccessibility is considered an important determinant of malnutrition. The poor cannot purchase adequate amount of food of the desired quality for meeting their and their family's nutritional requirements. On the other hand, food becomes inaccessible for people in situations such as civil wars, or natural calamities. Natural disasters such as floods, earthquakes, and droughts shift the precarious nutritional balance towards the negative side. However, it is the poor quality of food, rather than a quantitative deficit, which is responsible for malnutrition in majority of cases.

### *Social Factors*

Repeated pregnancies, inadequate child spacing, food taboos, broken homes and separation of a child from parents are responsible for quantitative and qualitative deficit of food and nutrients. Share of women and preschool children is disproportionately less compared with the economically active male adults. Families may also have irrational beliefs about the nutritional needs of infants and nutritional quality of common foods. Some foods are erroneously believed to be hot or cold in nature or likely to cause liver disease.

Undernutrition has a strong negative relationship with the mother's education. The percentage of children who are severely underweight is almost five times as high for children whose mothers have no education as for children whose mothers have 12 or more years of education. Risk of undernutrition is generally lower for first and consistently increases with increasing birth order. Short birth intervals are associated with higher levels of undernutrition. Rapid succession of pregnancies adversely affects the nutritional status of the mother leaving her malnourished and inappropriate lactation. Per capita availability of food in large families is low and unequally distributed.

## VITAMIN A DEFICIENCY (VAD)

(Also see Chapter 22.9)

Vitamin A deficiency of sufficient duration or severity can lead to xerophthalmia, childhood blindness, anemia, decrease host resistance to infection, and increased risk of mortality in under-five children. Vitamin A supplementation is shown to reduce the risk of death by 23–30% in children 6–59 months old.

Vitamin A deficiency (VAD) in a community is assessed by the prevalence of night blindness and serum retinol level ( $< 0.7 \mu\text{mol/L}$ ) in preschool children. Regions are categorized as having mild, moderate, or severe VAD, based on cut-offs listed in **Table 1**.

**Table 1** Indicators for recognizing vitamin A deficiency in the community

<i>Vitamin A deficiency in the community</i>	<i>Prevalence of night blindness in preschool children</i>	<i>Serum retinol <math>&lt; 0.70 \mu\text{mol/L}</math> in preschool children</i>
Mild	0–1%	2–10%
Moderate	1–5%	10–20%
Severe	$> 5\%$	$> 20\%$

Source: World Health Organization, 2009.

## Global Situation

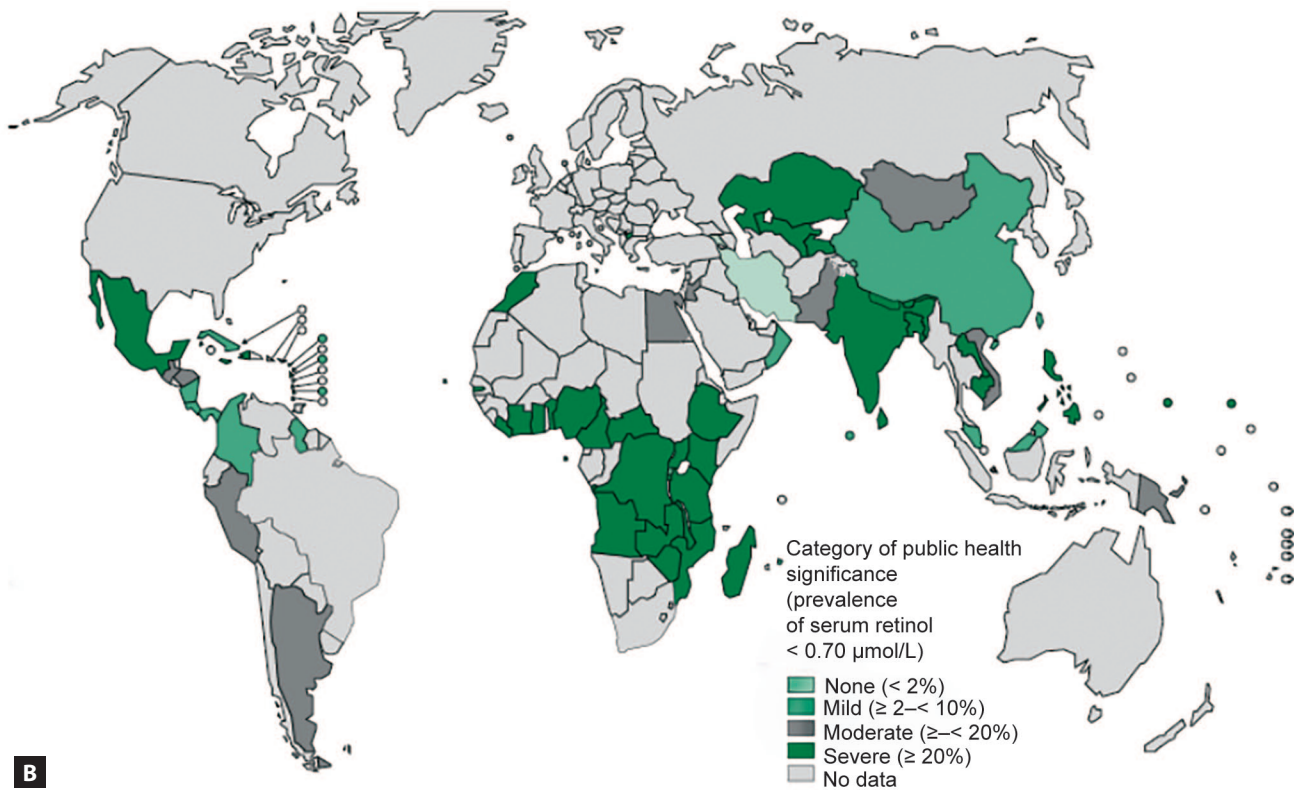

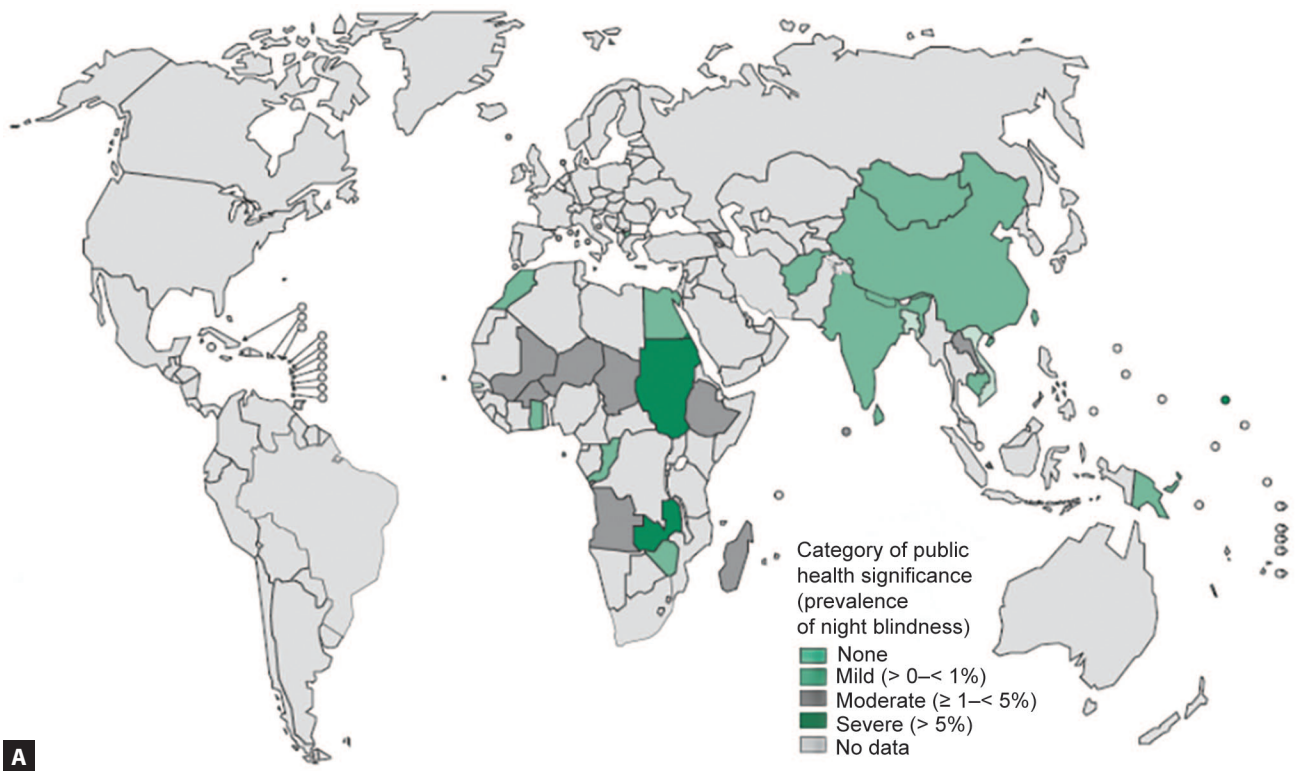

Night blindness affects more than 5 million preschool children and almost 10 million pregnant women, corresponding to 1% and 8% of global population, respectively. Biochemical deficiency affects 33.3% (190 million) of the preschool age population and 15.3% (19.1 million) of the pregnant women. Highest prevalence of VAD is accounted for by South-East Asia and Africa. **Figures 4A and B** categorizes the countries by degree of vitamin A deficiency in preschool children.

## India

As per WHO estimates, the prevalence of night blindness in under-five children and pregnant women in India is 0.6% and 12.1%; while that of biochemical deficiency (retinol  $< 0.7 \mu\text{mol/L}$ ) is 62% and 16.4%, respectively. Thus, subclinical vitamin A deficiency is a significant problem in preschool children, while overt vitamin A deficiency rampant in pregnant women. The National Nutrition Monitoring Bureau (NNMB) micronutrient survey (2006) indicates that there has been substantial decline in prevalence of Bitot spots in preschool children. The current prevalence of Bitot spots is only 0.7%; and prevalence of night blindness is less than 0.5%. According to countrywide data from department of women and child development, the overall prevalence of Bitot spots in India is 0.2%; ranging from 0.1% in Haryana and Himachal Pradesh to 3% in Mizoram. Prevalence of VAD is maximum in southern states of India; which may be related to dietary habits.

## Etiology

Dietary deficiency is the predominant etiology. Low intake of protective foods such as vegetables particularly green leafy vegetables, fruits and cereal-pulse based diets makes the Indian food deficient in vitamin A. Lack of exclusive breastfeeding also contributes to deficiency. Vitamin A absorption is hampered in chronic diarrhea, malabsorption states, and chronic liver disease. Depletion of vitamin A also occurs during acute infections. Frequent episodes of diarrhea, respiratory tract infections and measles increase the vitamin A demands making children prone to its deficiency during these states. Knowledge and practices of

**Figures 4A and B** Vitamin A deficiency as assessed by prevalence of (A) night blindness and (B) biochemical deficiency in preschool children (1995–2005 WHO survey data)  
Reproduced with permission from WHO, 2009.

women on vitamin A deficiency is poor and there is no prioritization for intake of dark green leafy vegetables and yellow colored fruits, which are rich in vitamin A.

## IRON DEFICIENCY ANEMIA

(Also see Chapter 38.6)

Iron deficiency anemia (IDA) is the most widespread micronutrient deficiency in the world, affecting more than 1.5 billion people. It is generally assumed that 50% of cases with anemia are due to iron deficiency. Anemia can result in impaired cognitive performance, suboptimal behavioral and motor development, in coordination, delayed language development and scholastic achievement, as well as increased morbidity from infectious diseases. Anemia in pregnancy is associated with increased maternal and child mortality and increased prevalence of low birthweight infants.

### Global Situation

Anemia affects 1.62 billion people (24.8%) across the world. Infants, children and pregnant women are the most vulnerable. Prevalence of anemia is highest in preschool age children (47.4%). One-fourth (25.8%) of all school-age children are anemic. South-East Asia and Africa are the worst affected (Fig. 5).

### Prevalence in India

Anemia is highly prevalent among the under-five children, and pregnant women, in every state of India. Among children 6–35 months it has increased from 74% in NFHS-2 to 79% in NFHS-3. The prevalence of anemia is highest in the age group of 12–23 months; this may partly be attributed to the initiation of weaning-infection coupled with poor nutritional supplementation.

### Etiology

Iron deficiency may be secondary to inadequate intake, decreased absorption, and/or increased losses. During infancy, milk is usually a major part of the diet. Both human milk and cow's milk provide relatively small quantities of iron (0.2–0.4 mg/L), but the bio-availability of iron from human milk is considerably higher than that of cow's milk. Hence, infants fed on cow's milk often develop iron deficiency anemia. Cereals and pulses which form the staple in complementary food are relatively poor in iron. Vegetables and iron rich animal proteins form a very small part of the diet. The Indian diet also contains large quantities of phytates, oxalates, phosphates, etc., all of which interfere with iron absorption.

Heavy parasitic infestation is an important cause of anemia in older children. Hookworm infestation results in large amount of blood loss. It is estimated that a hookworm can, on an average, remove 0.03–0.2 mL of blood per day. Chronic inflammation and infection can lead to depression of several indicators of iron status, like serum iron and increase in free erythrocyte protoporphyrin.

Puberty menorrhagia is an important cause of anemia among adolescent females. Anemia status of the child is closely linked with the anemia status of the mother. Each pregnancy and parturition results in large amounts of blood loss and several such pregnancies at short intervals make these women severely anemic. Children born to such mothers also have low iron stores. Children born to sociodemographically deprived mothers are also more likely to be anemic due to the inappropriate choice of food or due to food fads. Low-birthweight infants have a higher risk for iron deficiency as they have less iron stores at birth.

## IODINE DEFICIENCY DISORDERS (IDD)

(Also see Chapter 22.13)

Iodine deficiency disorders (IDD) refer to the wide spectrum of effects of iodine deficiency on growth and development. It includes

endemic goiter, endemic cretinism, impaired mental function and increased stillbirths and perinatal and infant mortality. Children living in iodine-deficient areas on an average have lower intelligence quotient (about 13 points) as compared to children living in iodine-sufficient areas.

### Global Situation

Iodine deficiency disorders (IDD) are a major health problem particularly among preschool children and pregnant women. It is the leading cause of preventable brain damage in the world. Globally, two billion people are at risk of iodine deficiency disorders due to insufficient iodine intake. Nearly 266 million school-aged children in the world have insufficient iodine intake. Some 38 million children are born every year unprotected against the risk of iodine deficiency. Among the 130 countries which reported data for IDD in 2006 (comprising 91.1% of the total global population) IDD is currently a significant public health problem in 118 countries (Fig. 6).

### Prevalence in India

About 350 million people, who do not consume iodized salt, are at risk for IDD. A recent study (IJMR, 2013) has reported 263/325 districts of India as IDD endemic (prevalence > 10%). Only 70% households consume adequately iodized salt. About 90,000 stillbirths and neonatal deaths occur every year due to maternal iodine deficiency. Around 54 million persons are estimated to have goiter, 2.2 million have cretinism and 6.6 million suffer from mild psychomotor handicaps. The overall prevalence of total goiter rate (TGR) among rural children (6–12 years) was about 4% (NNMB, 2001). The prevalence of goiter was highest in Maharashtra (11.9%) and West Bengal (9%).

### Etiology

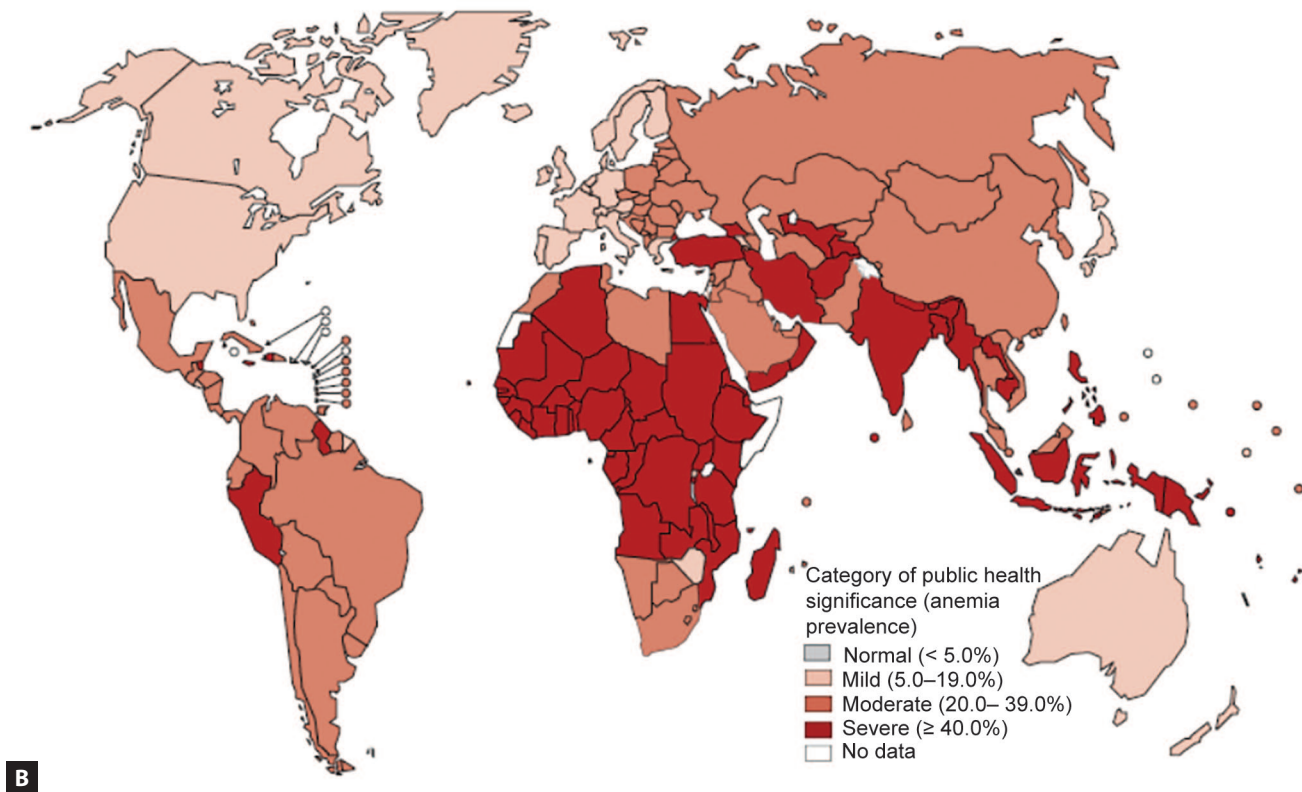

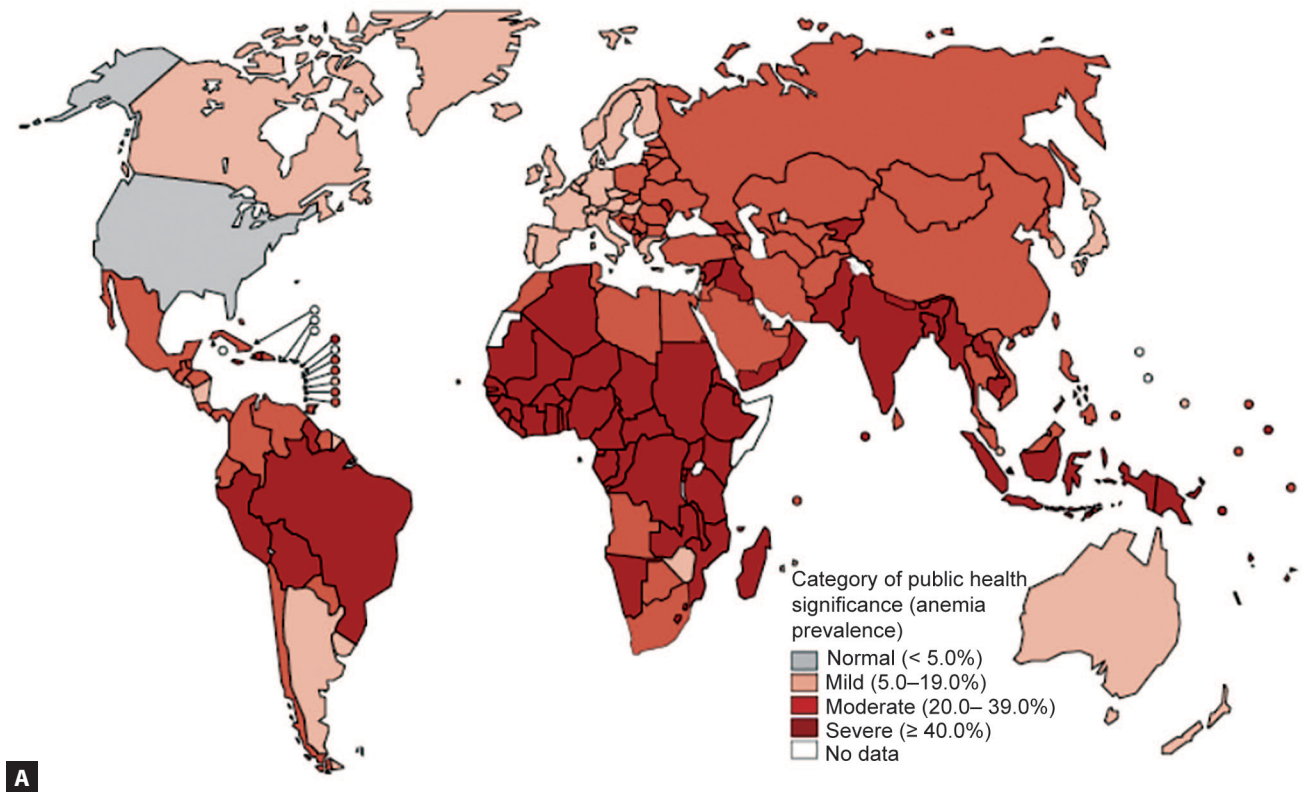

Iodine deficiency disorders (IDD) are connected to iodine deficient soil. Due to flooding, deforestation, glaciations, and changing rivers course the iodine present in top soil is drained constantly. This results in deficiency of iodine in crops grown on iodine deficient soil which in turn leads to low iodine in the diet. Pregnant women have increased requirement of iodine and if mothers do not have adequate iodine intake, babies may develop cretinism. Moreover, iodized salt coverage is still not complete and uniform across the country.

## FOOD SECURITY

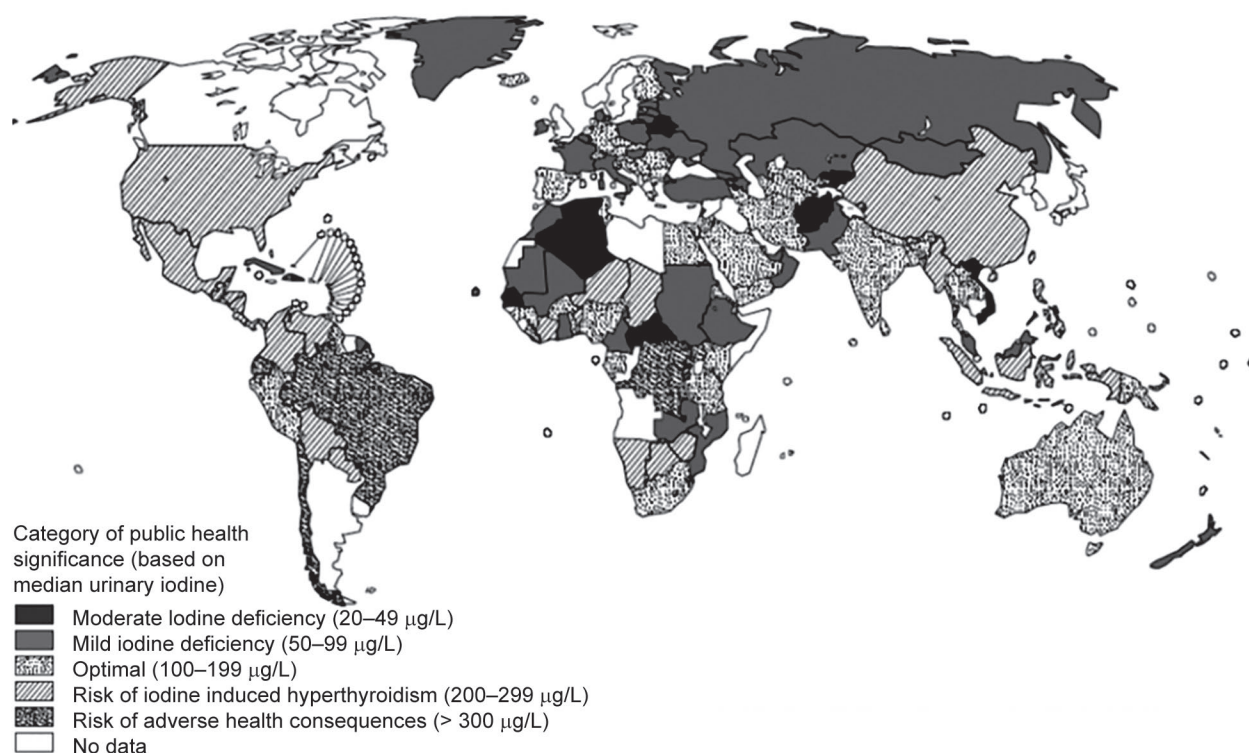

Nutrition security implies *physical, economic and social access to balanced diet, clean drinking water, safe environment, and health care*. The notion of food security rests on three distinct pillars, i.e., access, production and decision about food. Access to food implies physical and economic access to sufficient amounts of nutritious, safe and culturally appropriate foods. Production of food denotes the production methods that are economically viable, socially responsible and environmentally sustainable. Here what needs to be underlined is that while the producers should be able to generate a decent income, the consumers should have a sizeable disposable income to afford appropriate food. And the third pillar, i.e., decision ensures that people are capable of making informed choices about what they eat.

It is worthwhile to note that food security is not just a matter of food or hunger, but it encompasses several other dominant area of human development such as health, education and jobs. The government of India has introduced a Food Security Act (2013) that specifically includes provisions for prevention and management of child malnutrition, nutritional support to children, pregnant women and lactating mothers. The Act stated *to provide for food*

### IN A NUTSHELL

1. Undernutrition can be categorized as macronutrient (protein, fat, and carbohydrates) and micronutrient (vitamins and minerals) deficiency.
2. Macronutrient deficiency results in various syndromes of undernutrition including protein-energy malnutrition (PEM), underweight, stunting, and wasting.
3. Severe acute malnutrition is the most severe form of macronutrient deficiency. It is almost always associated with multiple micronutrient deficiencies.
4. The most important micronutrient deficiencies are those of iron, iodine and vitamin A, resulting in nutritional iron deficiency anemia (IDA), iodine deficiency disorders (IDD), and xerophthalmia, respectively.
5. Food security implies provision for food and nutritional security in human life cycle approach, by ensuring access to adequate quantity of quality food at affordable prices to people to live a life with dignity.

## Chapter 22.6

# Pathophysiology of Undernutrition

OP Mishra

Undernutrition in children occurs due to an imbalance between nutrient requirement and intake leading to deficits of energy, protein, or micronutrients that may negatively affect growth and development. Imbalance between nutritional intake and requirement leading to calorie and/or protein deficiency is coupled with micronutrient deficiencies. As a result there is decrease in lean body mass, muscle weakness, development of edema, immune dysfunction and the risk of recurrent infections. Generalized changes in different organs can cause decreased intake of foods, anorexia, malabsorption, nutrient loss in chronic or recurrent diarrhea and increased energy requirement resulting into undernutrition. The condition is further aggravated by poverty, illiteracy, unhygienic feedings, prolonged starvation during illness and chronic systemic disorders. High prevalence of low birthweight babies and lack of exclusive breastfeeding are the two important factors which lead to high incidence of undernutrition in the developing countries. The two severe forms of undernutrition such as marasmus and kwashiorkor are the result of these physiological alterations.

### THEORY OF ADAPTATION (GOPALAN, 1967)

Gopalan proposed that marasmus represents the extreme form of adaptation to chronic calorie deficiency, while edematous kwashiorkor is the reflection of failure of adaptation to protein deficiency. The adrenocortical response to stress due to protein and calorie deficiency determines the development of these two forms of undernutrition. Detailed pathogenesis is described in **Flow chart 1**.

### THEORY OF FREE RADICAL INJURY (GOLDEN, 1987)

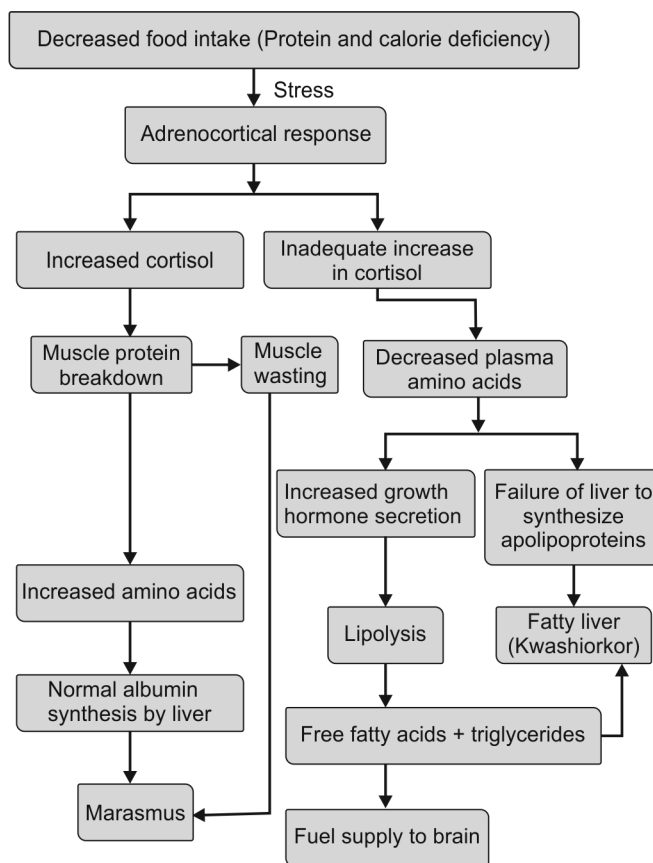

Several etiological factors such as dietary protein deficiency, aflatoxins in food and decreased protein deficiency compounded by infection have been proposed for causation of kwashiorkor. Golden proposed the theory of free radical injury causing cellular damage and exceeding the antioxidant defense mechanism in these patients. Subsequently various studies have demonstrated that children with kwashiorkor had higher concentrations of biomarkers of oxidative stress and lower levels of antioxidants than marasmus and normal healthy controls. The levels of oxidative stress showed normalization after recovery from kwashiorkor. Later, it was shown that antioxidants have no protective effect in the development of kwashiorkor tested in an endemic zone of Malawi. However, it is premature to conclude that oxidants have no role in kwashiorkor as antioxidants consumption may have been in inadequate amount in comparison to oxidative stress in these children. Thus, etiopathogenesis of kwashiorkor could be multifactorial in origin and single factor may not be responsible for the causation of disease.

### CHANGES IN BODY COMPOSITION AND FUNCTION

#### Water and Electrolytes

The total body water is increased in these children. There is more extracellular fluid than intracellular fluid and is found especially

**Flow chart 1** Adrenocortical response and biochemical changes in undernutrition

in edematous children. Marasmic children have the highest total body water and reduced adipose and lean body mass. Body fluid compartments are affected by many factors including nutritional and disease states such as dehydration or fluid overload. Total body sodium is increased. Potassium is low. Dilutional hyponatremia can occur in children with fluid retention or acute kidney injury following acute gastroenteritis. While treating diarrheal dehydration in children with severe malnutrition, it is important not to overload them with fluid or sodium.

#### Plasma Proteins

Hypoproteinemia is commonly found in protein energy malnutrition. Plasma levels of albumin and some fractions of glycoproteins are decreased. Protein binding of some of the drugs is decreased and as a result there can be free drug levels in plasma. Low plasma albumin level is partly responsible for edema in kwashiorkor. Inadequate production of beta-lipoproteins results in an impaired transport of fat from liver leading to fat accumulation in liver and fatty liver. Development of edema in kwashiorkor is multifactorial in origin and is due to low albumin level, free radical injury and inadequate inactivation of antidiuretic hormone by liver leading to water retention.

#### Coexisting Nutrient Deficiencies

Multiple coexisting nutrient deficiencies can be present due to decreased intake, malabsorption and losses in recurrent or persistent diarrhea. Malabsorption occurs due to villus atrophy and secondary enzyme deficiencies. The most common being lactase deficiency leading to lactose intolerance. Nutrients like iron, zinc

and vitamins such as riboflavin, folic acid, vitamin B<sub>12</sub>, C and A can be affected in severe undernutrition and can show their clinical signs and symptoms of deficiencies. As such overt features of rickets are not seen in undernutrition, but become evident during nutritional rehabilitation if vitamin D supplementation is not given.

### Immunity

Overall there is generalized depression in immunity. Lymphoid organs such as lymph nodes, tonsils and thymus are atrophied. There is low complement levels and decreased synthesis of secretory IgA. Cell-mediated immunity is impaired and there is an inadequate response to vaccine antigens. Delayed hypersensitivity reaction to purified protein derivative is impaired in severe undernutrition. There is defective phagocytosis and the typical features of infection such as leukocytosis and fever are absent. Humoral immunity is less affected. Physical barrier such as skin is compromised as it is thin and broken and makes easy entry to microorganisms.

### Gastrointestinal Tract

Gastric acid production is reduced. There is atrophy of pancreas and small intestinal mucosa and overall digestive enzymes are decreased. Malabsorption of nutrients occurs and there is recovery after nutritional rehabilitation. Villus atrophy of jejunal mucosa not only affects the nutrients but also drug absorption. Synthesis of proteins by liver is decreased. The capacity of liver to metabolize and inactivate toxins is severely affected. Liver biopsy shows fatty changes, abnormal rough endoplasmic reticulum and mitochondria and decreased peroxisomes. There is decreased gluconeogenesis resulting in to high incidence of hypoglycemia especially during stress such as infection.

### Central Nervous System

The undernutrition at an early age has important impact on the developing brain. The dendritic arborization and morphology of the dendritic spines as well as myelination are affected. Computerized tomography and magnetic resonance imaging of brain have shown features of cerebral atrophy in children suffering from undernutrition. This affects the higher brain functions and may lead to permanent neuropsychological damage. Cognitive function and learning abilities remain affected even after nutritional rehabilitation.

### Circulatory System

The blood pressure is low due to decreased cardiac output and stroke volume. They have small and thinner heart. Plasma volume is normal, but higher chance of decreased tissue perfusion in state of dehydration. Children with edematous undernutrition have greater chance of development of congestive cardiac failure if any fluid is rapidly infused as circulation overload occurs more easily than normal children due to more sodium and water retention. The basal metabolic rate is reduced to about one-third. Heat generating capacity and protection are reduced as a result there is a greater chance of hypothermia.

### Renal System

The capacity of kidney to excrete excess water or acid is reduced. There is decreased sodium and phosphate excretion. These children have higher incidence of urinary tract infection due to changes in urinary tract epithelium. The serum urea and creatinine levels are normal except in state of dehydration, and it improves following fluid resuscitation. There is no established renal damage in these children, but edema seen in kwashiorkor and marasmic kwashiorkor has been attributed to impaired fluid and sodium excretion in addition to contribution by hypoproteinemia.

## Endocrine System

Endocrine glands play a major role in the process of adaptation in response to stress to protein and calorie deficiency. Almost most of the major hormones are affected in children suffering from chronic undernutrition.

### Cortisol

Cortisol is the major glucocorticoid produced by adrenal cortex. This hormone plays a major role in adaptation to protein and calorie deficiency in these children. Although there is atrophy of adrenal cortex and medulla, good functional reserve is seen in response to corticotropin. When these children are not having any acute stress over their undernutrition, their plasma cortisol level remains normal. But its level is found to be increased when complicated by infection, acidosis, hypoglycemia and hypothermia. The adrenocorticotropin (ACTH) levels are normal despite increase in cortisol levels. Plasma aldosterone level is normal but rate of secretion is increased in marasmus. In contrast, its level is increased in kwashiorkor in spite of normal secretion rate and this is due to decreased metabolism by liver. Further, these abnormalities normalize after nutritional rehabilitation.

### Insulin

There are changes in islets of Langerhans cells of pancreas in chronic undernutrition. Insulin level is low in kwashiorkor and decreased response to intravenous glucose or glucagon is found. Glucose tolerance is impaired in kwashiorkor while it is normal in marasmus. The impaired glucose tolerance may be due to poor insulin release in response to stimulus, insufficient utilization by peripheral tissues, decreased potassium and deficient diet in chromium. The defect in insulin release might be due to either structural damage to beta cell by undernutrition or defective stimulation of insulin release. Glucagon levels have been found to be variable depending upon the involvement of alpha cells.

### Growth Hormone

The response of pituitary gland to secrete growth hormone (GH) mainly depends upon the type of malnutrition. Plasma GH levels are high in kwashiorkor, while reported to be normal, decreased or increased in marasmus. The high GH in kwashiorkor does not respond further to arginine stimulation and falls only when protein is added in the diet. Low fasting levels of insulin and negligible response to hyperglycemia is an adaptive response to fuel supply to brain. Thus, low insulin level acts as a primary regulator of peripheral fuel release and high GH is to provide substrate in response to malnutrition. Somatomedin A and insulin-like growth factors are decreased in kwashiorkor in comparison to marasmus.

### Thyroid Hormones

It has been demonstrated that there is hypofunction of thyroid gland as there is decreased basal metabolic rate, decreased protein-bound iodine, decreased I<sup>131</sup> uptake and low plasma T4 level. The decreased levels of thyroxine-binding prealbumin and globulins are due to decreased synthesis by liver. The low T3 level found in kwashiorkor is due to impaired deiodination in liver. The thyroid-stimulating hormone (TSH) levels are normal and its response to thyrotropin-releasing hormone (TRH) is sustained; indicating good pituitary reserve. There is dramatic catch-up growth following nutritional rehabilitation.

### Gonadotropins

The negative influences of undernutrition and persistent deprivation cause delayed puberty in these children. Menarche in girls is delayed. Failure of maturation of reproductive organs and delay in appearance of secondary sexual characteristics have been observed.

### IN A NUTSHELL

1. Undernutrition is a common public health problem in under-5 children and of multifactorial in origin.
2. Theories of adaptation and free radical injury have been proposed for its pathogenesis.
3. Total body water and sodium are increased; and potassium is decreased in severe malnutrition. Overzealous therapy of dehydration may lead to fluid overload or congestive heart failure.
4. Generalized changes in different systems occur in severe undernutrition and responsible for systemic manifestations.
5. Adrenocortical response to stress of protein and calorie deficiency plays key role in the development of marasmus and kwashiorkor.

## Chapter 22.7

# Protein Energy Malnutrition

KE Elizabeth

In 1959, Jelliffe coined the term protein calorie malnutrition (PCM) to include all clinical types of malnutrition. The International System of Units proposed the replacement of the term *calorie* by *Joule* (1 cal = 4.184 J) as a unit and the term *energy* for general use. This has resulted in the term protein energy malnutrition (PEM) instead of PCM. World Health Organization (WHO) defined the term PEM as a range of pathological conditions arising from coincident lack, in varying proportions of protein and calories, occurring most frequently in infants and young children and commonly associated with infections. The term is preferably used for infants and young children.

## SPECTRUM OF PROTEIN ENERGY MALNUTRITION

### Kwashiorkor

Professor Cicely Williams in 1933 from Gold Coast described kwashiorkor. She observed that this was the disease of the first child when the second was on the way displacing the first child from the breast. She named it kwashiorkor. Later on, the term was interpreted as the disease of the *deposed child*. Workers from West Indies identified a syndrome similar to kwashiorkor with prominent cheeks and edema and suggested the term *sugar baby* to stress the dietary origin of the disease. A classic case of kwashiorkor is apathetic, miserable, stunted in growth and has edema, hepatomegaly, anemia and hair and skin changes (**Fig. 1**). The skin changes are collectively referred to as *nutritional dermatosis*. Cutaneous manifestations also include flaky paint dermatitis and crazy pavement dermatosis. The triad of essential features of kwashiorkor consists of growth retardation, edema, and mental changes. A grading of kwashiorkor has been proposed as: Grade I, pedal edema; Grade II, pedal and facial edema; Grade III, pedal, facial, paraspinal, and chest edema; Grade IV, generalized edema with ascites.

**Figure 1** Skin changes, hair changes and edema in an infant with kwashiorkor

### Marasmus

The word marasmus is derived from the Greek word *marasmos*, which means *wasting*. Affected children exhibit extreme wasting and have an *old man appearance* with just skin and bones (**Fig. 2**). The wasting of the brown fat occurs first because it is metabolically more active and is important in thermogenesis. Children with marasmus are generally alert and have good appetite. Later on they become irritable. When marasmic children develop edema, it is termed marasmic kwashiorkor. A grading of marasmus has been proposed as: Grade I, loose skin folds in axilla and groin; Grade II, loose skin folds in thighs and buttocks; Grade III, wasting of chest and abdomen; and Grade IV, wasting of buccal pad of fat.

**Figure 2** A marasmic infant with irritability, loose skin folds in the axilla, thigh, buttocks, chest and face

**Nutritional dwarfing** Prolonged nutritional insult starting early in life and going on chronic without developing kwashiorkor or marasmus results in nutritional dwarfing.

**Underweight** The child is malnourished, but does not have any features of marasmus or kwashiorkor. The weight-for-age (WFA) is between 60% and 80% of the expected.

## ASSESSMENT OF MALNUTRITION

Assessment of nutritional status can be done by evaluating the following ABCDEF:

- Anthropometric assessment
- Biochemical assessment
- Clinical assessment
- Dietary assessment including feeding practices
- Epidemiological and ecological assessment
- Functional assessment for organ function and morphology

### Anthropometric Assessment

Anthropometry is a simple valuable tool and the gold standard for evaluating the nutritional status, but it has many limitations. Adequate precautions are to be taken during measurement and the procedures utilized are to be standardized and checked frequently for accuracy. Intraobserver and interobserver reliability should be established first, measurements must be taken according to the standardized techniques and the equipment should be checked periodically for accuracy. Anthropometric criteria can be categorized as *age-dependent* and *age-independent*.

### Age-dependent Anthropometric Measurements

These include weight, length or height, head circumference noted against the exact age in years and months. These measurements are then compared with median, other percentiles, or Z-score in the reference standards like regional or WHO growth charts.

**Weight-for-age** It indicates the appropriateness of weight for that particular age, in the given child, on the basis of which the child can be labeled as being normal or underweight. WFA less than expected may be due to undernutrition, intrauterine growth retardation, low birthweight, endocrine causes, genetic or chromosomal conditions, syndromic conditions and systemic illness. WFA can be represented as percentage of the expected assuming 50th centile as 100% as per Gomez or Indian Academy of Pediatrics (IAP) Classification (**Table 1**); or as percentile like 50th, 25th, 10th, 5th, 3rd percentile; or as between  $-1Z$  and  $+1Z$  (normal), between  $-1Z$  and  $-2Z$  (mild), between  $-2Z$  and  $-3Z$  (moderate) and more than  $-3Z$  (severe) grades of underweight. The recent general agreement is to use WHO Z-scores for ease of interpretation into mild to moderate or severe underweight. The Gomez classification (1956) and the IAP classification (1972) are based on percentage of the present weight as against the expected weight. The disadvantage of WFA is that it may not be the true reflection of undernutrition, and low weight may also be due to short stature, intrauterine growth restriction, syndromic conditions and endocrine or metabolic causes.

**Length or height-for-age** It indicates grade of stunting in a child, which may be due to chronic malnutrition, short stature, skeletal dysplasia, endocrine causes, genetic or chromosomal conditions, syndromic conditions and chronic systemic diseases. It can also be represented or interpreted as percentage of the expected assuming 50th centile as 100% as per Waterlow or McLaren classification; or as percentile like 50th, 25th, 10th, 5th, 3rd centile; and or as between  $-1Z$  and  $+1Z$  (normal), between  $-1Z$  and  $-2Z$  (mild), between  $-2Z$  and  $-3Z$  (moderate) and less than  $-3Z$  (severe) stunting (**Table 2**).

**Table 1** Classification according to weight-for-age (underweight)

Classification Weight-for-age (% of expected)	Mild Grade I	Moderate Grade II	Severe Grade III	Severe Grade IV
Gomez	75–90%	60–75%	< 60%	-
Indian Academy of Pediatrics (IAP)*	71–80%	61–70%	51–60%*	< 50%
<b>Wellcome Trust Classification</b>				
with no Edema	Underweight 60–80%		Marasmus < 60%	-
with edema	Kwashiorkor 60–80%		Marasmic Kwashiorkor < 60%	-

\*IAP Classification: If the patient has edema of nutritional origin, the letter K is placed along with the grade of malnutrition in order to denote kwashiorkor

**Table 2** Classification according to height-for-age (stunting)

Height-for-age (% of expected)	Waterlow's classification	McLaren's classification
Normal	> 95	> 93
First degree stunting/Short*	90–95	80–93
Second degree stunting	85–90	-----
Third degree stunting/Dwarf*	< 85	< 80

\*Terminology used in McLaren's classification

The present consensus is in favor of using WHO Z-score charts for interpretation of HFA.

**Weight-for-height** It indicates the degree of wasting, which is due to acute malnutrition. It can also be represented or interpreted as percentage of the expected assuming 50th percentile of the WHO WFH growth charts as the expected length or height. Wasting can also be classified as per Waterlow/McLaren/WHO classification (**Table 3**); and/or as percentile like 50th, 25th, 10th, 5th, 3rd percentile and or as between  $-1Z$  and  $+1Z$  (normal), between  $-1Z$  and  $-2Z$  (mild), between  $-2Z$  and  $-3Z$  (moderate) and less than  $-3Z$  (severe) wasting (**Table 3**). WHO has suggested a comprehensive classification of malnutrition based on HFA, WFH, and presence of edema (**Table 4**).

**Head circumference and chest circumference** At birth, the head circumference is more than the chest circumference and both equalize by 1 year. Thereafter, the chest circumference is more than the head circumference. In malnutrition, chest circumference will remain less than head circumference after infancy.

**Skinfold thickness (SFT)** The skinfold thickness at triceps is measured to the nearest 0.1 cm by means of the *Harpender calipers*. This gives an indication of the subcutaneous fat and indirectly the calorie reserve in the body. Subscapular SFT can also be measured under the scapula. This is currently used for research purpose only.

### Age-independent Anthropometric Measurements

**Mid-upper arm circumference (MUAC)** Between 6 months and 60 months of age, MUAC can be used to classify malnutrition (**Table 5**). *Shakir shape* is a colored tape indicating normal

**Table 3** Classification according to weight-for-height (wasting)

Weight-for-height (% of expected)	Waterlow's classification	McLaren's classification	WHO classification
Normal	> 90%	> 90%	
First degree wasting/mild wasting*	80–90%	85–90%	
Second degree wasting/moderate wasting*	70–80%	75–85%	Between $-2Z$ to $-3Z$ score or 70–79% of expected (median)
Third degree wasting/severe wasting*	< 70	< 75	< $-3Z$ score or less than 70% of expected (median)

\*Terminology used in McLaren's classification

**Table 4** WHO classification for assessment of malnutrition

	Moderate undernutrition	Severe undernutrition
Symmetrical edema	No	Yes <sup>a</sup> Edematous malnutrition
Weight-for-height (measure of wasting)	Z score <sup>b</sup> $-2$ to $-3$ (70–79% of expected <sup>c</sup> ) Wasting	Z score $< -3$ ( $< 70\%$ of expected) Severe wasting
Height-for-age (measure of stunting)	Z-score <sup>b</sup> $-2$ to $-3$ (85–89% of expected <sup>c</sup> ) Stunting	Z-score $< -3$ ( $< 85\%$ of expected) Severe stunting

a. This includes kwashiorkor and marasmic kwashiorkor

b. Z (SD) score =  $\frac{\text{Observed value} - \text{expected value}}{\text{Standard deviation of reference population}}$

c. Median (50th percentile of WHO standards)

**Table 5** Classification according to mid-upper arm circumference (MUAC) (6–60 months)

MUAC (cm)	Interpretation
> 13.5	Normal
12.5–13.5	Mild to moderate malnutrition
11.5–13.5	Severe malnutrition
< 11.5	Severe acute malnutrition (SAM)*

\*If length < 66 cm, MUAC < 11 cm

nutritional status (green), mild to moderate malnutrition (MAM) (yellow) and severe malnutrition (red) instead of numbers used in MUAC. *Bangle test* is applied by slipping a bangle of internal diameter of 4 cm, if it slips into the axilla in an under-5 child, it indicates undernutrition.

### Biochemical Assessment

Biochemical changes include lowering of serum protein, especially the albumin fraction, enzymes like esterase, amylase, lipase, cholinesterase, alkaline phosphatase and lactic dehydrogenase, carrier proteins like transferrin, ceruloplasmin and beta-lipoprotein, essential amino acids, essential fatty acids, serum calcium, phosphorus, potassium, iron, and magnesium. Serum protein electrophoresis may show low albumin band and low alpha-2 beta-globulin bands. Alpha-2 globulin and beta-globulin bands represent the carrier proteins. The alpha-1 globulin band that represents acute phase reactants and gamma-globulin band that represents antibodies produced against infection may be raised. Reduction in carrier proteins is an early indicator of PEM. The synthesis of acute phase reactants is given more priority in protein deficiency states than the synthesis of carrier proteins. Urinary creatinine, an indirect evidence of muscle mass may be low.

### Clinical Assessment

The clinical signs vary based on the spectrum of the disease, namely underweight, marasmus, and kwashiorkor. Almost all organs in the body can be affected.

**Growth retardation** This is the most important feature of PEM, evidenced by weight loss, wasting and stunting. Growth retardation is present in both kwashiorkor and marasmus.

**Edema** It is seen in kwashiorkor and marasmic kwashiorkor. Mooning of face is often noted in kwashiorkor. Effusion into the serous cavities may occur in severe edema. Isolated ascites may be due to associated liver disease or intestinal tuberculosis.

**Mental changes** Irritability and apathy are the common changes noted in PEM. They are multifactorial in origin. Affected children fail to interact with the environment and also with the mother. Social smile regresses. Brain edema, electrolyte imbalances, hypokalemia and hypomagnesemia are suggested to be the causes. Alteration in neurotransmitter synthesis and release is found to be another major cause. PEM reduces playful exploratory activity, motivation and arousal.

**Hepatomegaly** This is due to fatty infiltration, which starts in the periphery of the lobule and gradually extends to the center. Histologic evidence will be present, even when fatty liver is not clinically evident.

**Hair changes** The changes are more evident at the root of the hair in acute PEM. The hair becomes sparse, easily pluckable and hypopigmented (hypochromotrichia). In some children, the hair becomes red and this led to the term red boy to denote

kwashiorkor. When the nutritional status is regained, the root becomes pigmented and the tip is seen hypopigmented (*flag sign*). There may also be straightening of curly hair and change in texture.

**Skin changes** These indicate severe degree of malnutrition and may occur rapidly in fatal cases. The skin becomes hypopigmented or hyperpigmented, erythematous or jet black in color. This *flaky paint dermatosis* is pathognomonic. It occurs more often in the extremities than trunk and the hyperpigmented patches peel off to expose raw or hypopigmented areas. The cracked lesion in the flexures, groin and buttocks which is infected and ulcerated is called crazy pavement dermatosis. Deficiencies of tyrosine, niacin, zinc and vitamins are attributed in the pathogenesis of these skin changes. Secondary infection with fungi and bacteria may occur. The term *nutritional dermatosis* is also applicable.

**Mucosal changes** Glossitis, stomatitis, and cheilosis are due to various vitamin deficiencies. Secondary infection may occur as candidiasis.

**Purpura or bleeding** It may be seen in those with gram-negative septicemia, disseminated intravascular coagulation and vitamin C and K deficiency.

**Tremors** These are characteristically seen during treatment. Deficiency of vitamin B factors due to increased demand, electrolyte imbalance, imbalance in the production of inhibitory substances like gamma-aminobutyric acid and demyelination are thought to be the causes. Frequent blinking, tremulous cry due to vocal cord tremor and tremors of the body designated *kwashi shake* are rarely noted. The tremors generally subside after some time.

Clinical signs of malnutrition, as identified by Jelliffe, are listed in **Table 6**.

### Dietary Assessment

A history is obtained regarding breastfeeding, complementary feeding, and family pot feeding. Feeding practices are also ascertained. An overall assessment of average food intake (prior to the illness) is possible by a *24-hour recall method*. Average of a 3-day recall during the mid-week (and not including a festival day) is recommended. A food frequency table to record the frequency of intake of each food item is also desirable, i.e., thrice a day, once a day, twice a week, etc. The standard serve for each item has to be defined prior to this. Weighting the uncooked as well as the cooked food and then assessing the nutritive value of food eaten are the other methods, but often not practical. The service of a dietitian is ideal for accurate assessment. The calculated intake should be finally compared with the recommended dietary allowances for the age. A rough idea about the adequacy of micronutrients like vitamins and minerals in the diet should also be obtained. Diet during illness also should be evaluated including any exclusion diets. Maternal beliefs regarding diet during common childhood illnesses are often wrong and unscientific. It is not uncommon to starve the child during diarrhea, measles, respiratory infection, etc. Mothers must be taught to continue feeding during illness and to select easily digestible food items during illness.

### Epidemiological and Ecological Assessment

Socioeconomic assessment, vital statistics like infant mortality, neonatal mortality, perinatal mortality, still birth and under-5 mortality rate (U5MR) are the usual indicators selected to evaluate the nutritional status of a community. When the nutritional status improves, morbidity and mortality will come down. In an individual child also, the socioeconomic status, morbidity, etc. can be evaluated.

### Functional Assessment

Organ dysfunction, delayed developmental milestones, vision and hearing impairment attributable to deficiencies should

**Table 6** Clinical signs of malnutrition (Jelliffe)

<i>Organ</i>	<i>Signs</i>	<i>Cause</i>
Hair	Lack of luster Thinness and sparseness Straightness Dyspigmentation Flag sign Easy pluckability	Protein and micronutrient deficiency
Face	Diffuse depigmentation Nasolabial dyssebacia Moon face	Riboflavin/multiple deficiency
Eyes	Pale conjunctiva Bitot's spots Conjunctival xerosis Corneal xerosis Keratomalacia Angular palpebritis	Iron, Folate/ B <sub>12</sub> deficiency Vitamin A deficiency
Lips	Angular stomatitis Angular scars Cheilosis	Riboflavin, iron deficiency
Tongue	Edema Scarlet and raw tongue Atrophic papillae	Riboflavin, iron deficiency
Teeth	Mottled enamel	Calcium, vitamin D deficiency
Gums	Spongy, bleeding gums	Vitamin C deficiency
Glands	Thyroid enlargement Parotid enlargement	Iodine deficiency
Skin	Xerosis Follicular hyperkeratosis Petechiae Pellagrous dermatosis Flaky paint dermatosis Scrotal and vulval dermatosis	Vitamin A, essential fatty acid deficiency  Vitamin C deficiency Thiamine deficiency Multiple deficiency
Nails	Koilonychia	
Subcutaneous tissue	Edema Amount of subcutaneous fat reduced	Protein, vanadium deficiency
Muscular and skeletal systems	Muscle wasting Craniotabes Frontal and parietal bossing Epiphyseal enlargement Beading of ribs (tender/nontender) Wide open anterior fontanel Knock-knees or bow legs Diffuse or local skeletal deformities Deformities of thorax Musculoskeletal hemorrhages	Protein deficiency Vitamin D deficiency  Vitamin D, vitamin C deficiency  Vitamin C, K deficiency
Gastrointestinal tract	Hepatomegaly	Lipoprotein deficiency
Nervous system	Psychomotor change Mental confusion Sensory loss Motor weakness Loss of position sense Loss of ankle and knee jerks Calf tenderness	Iron, multiple deficiency  Vitamin B <sub>6</sub> , B <sub>12</sub> deficiency Protein, potassium, vitamin D deficiency Vitamin B <sub>6</sub> , B <sub>12</sub> deficiency Vitamin B <sub>6</sub> , B <sub>12</sub> deficiency Vitamin B, E deficiency
Cardiovascular system	Cardiomegaly Microcardia Tachycardia	Thiamine, selenium deficiency  Iron deficiency

be evaluated and documented. Morphological assessment of changes that occur in the buccal mucosa and hair shaft may be noted. In the buccal smear, above 70% of cells may be seen mutilated as against less than 10% in normal children. The hair shaft size is reduced and most of the cells in the growing end are noted to be in the resting phase of telogen and only very few in the growing phase of anagen. The mineral content of the hair root may also be reduced. Curly hair may straighten up in PEM. Difference in texture of hair is an early sign. X-ray of bones may be evaluated to look for rickets, and delayed bone age. The bone age usually corresponds to the height age rather than the chronological age. Transverse lines that represent periods of arrested growth at the growing end of long bones may be noted prior to the onset of frank PEM.

## INVESTIGATIONS

**Blood** Hemoglobin, complete blood counts, peripheral smear, blood sugar, urea, serum electrolytes, serum protein, albumin, serum calcium, phosphorus, alkaline phosphatase, blood culture; Mantoux test; X-ray chest; urine routine examination and culture; stool for ova and cyst, are usually needed for management. Liver function test, renal function test and lumbar puncture may be done whenever indicated.

## MANAGEMENT

Care of children with severe PEM is quite a challenging task as they often present with life-threatening medical emergencies. The various steps involved are treatment of life-threatening medical complications; restoration of WFH; and rehabilitation and prevention. These steps are detailed in the next chapter on management of severe acute malnutrition. Micronutrients also need to be supplemented. Cautious feeding is the rule starting with 75–100 kcal and 1 g protein/kg/day and slowly increasing, and reaching a goal of 150–220 kcal and 4–6 g protein/kg/day. MAM without medical complications can be treated at home under supervision on an ambulatory basis.

## PREVENTION

Ten key interventions are proposed by UNICEF for prevention of malnutrition (**Box 1**). These are particularly important during the first 1,000 days of life including 9 months (270 days) in utero plus first 24 months (730 days) after birth. The period of the first 1,000 days lays the foundation for growth, development, immunity, etc. By 2 years of age, weight becomes 20%, length becomes 50% and brain attains almost 80% of growth. Myelination is almost complete.

### BOX 1 Ten key interventions to prevent malnutrition

1. Timely initiation of breastfeeding within 1 hour of birth.
2. Exclusive breastfeeding during the first 6 months of life.
3. Timely introduction of complementary foods at 6 months.
4. Age-appropriate foods for children 6 months to 2 years.
5. Hygienic complementary feeding practices.
6. Immunization and biannual vitamin A supplementation with deworming.
7. Appropriate feeding for children during and after illness.
8. Therapeutic feeding for children with severe acute malnutrition.
9. Adequate nutrition and support for adolescent girls to prevent anemia.
10. Adequate nutrition and support for pregnant and breastfeeding mothers.

## IN A NUTSHELL

1. The spectrum of malnutrition extends from mild underweight to severe acute malnutrition and includes wasting, stunting, and severe forms such as marasmus and kwashiorkor.
2. Nutritional status can be assessed by anthropometric, biochemical, clinical, dietary, epidemiological and functional criteria.
3. Weight-for-age (WFA), height-for-age (HFA) and weight-for-height are useful indicators to assess presence of underweight, stunting, and wasting, respectively.
4. Wasting is an indicator of acute malnutrition while stunting indicates chronic nutritional deficit.
5. Z-scores as used in WHO growth charts provide an easier way for anthropometric assessment and interpretation.
6. Mild to moderate cases can be managed in home-based programs, while severely malnourished children need hospitalization.

## Chapter 22.8

# Severe Acute Malnutrition

Praveen Kumar, Preeti Singh

A child is said to be *underweight* if his or her weight-for-age (WFA) is low as compared to the standard for his or her age and sex [Z-score is less than two standard deviation below the median ( $< -2$  SD)] for the age and sex as per the accepted growth standard. Underweight can result from either acute or chronic malnutrition or both and it is thus a composite measure of stunting and wasting. *Wasting* indicates current or acute malnutrition resulting from failure to gain weight or actual weight loss, represented by low weight-for-height (WFH). *Stunting* is an indicator of linear growth retardation that results from failure to receive adequate nutrition over a long period or due to recurrent infections. Stunting is defined as height-for-age (HFA) less than  $-2$  Z-score. It is an indicator of past growth failure. **Table 1** provides a classification of nutritional status based on assessment of WFA, WFH and HFA. As stated in earlier chapter, mid-upper arm circumference (MUAC) is another indicator of malnutrition, independent of age. Nutritional status of a child can be assessed objectively against standard cut-offs for MUAC (**Table 2**).

Wasting or acute malnutrition is further graded into severe acute malnutrition (SAM) and moderate acute malnutrition (MAM) in children. It has been found that lower the Z-score or MUAC (mm), higher the risk of death. For children in whom WFH Z-score is less than  $-3Z$  and MUAC less than 11.5 cm, risk of mortality increases dramatically. However, in edematous children with SAM, accumulation of fluid may lead to W/H more than  $-3$  SD and even MUAC more than 11.5 cm but risk of mortality is even more than nonedematous SAM children. Hence, edema is included as independent criteria for identifying children with SAM (**Table 3**).

**Severe acute malnutrition** It is defined by presence of very low weight-for-height/length (SD score below  $-3Z$  of the median for WHO child growth standards), and/or mid-upper arm circumference less than 11.5 cm, and/or by the presence of bilateral pitting edema.

**Table 1** Classification of nutritional status

SD score	Indicators		
	Weight-for-age	Height-for-age	Weight-for-length/height
Median or below $-1$ SD	Normal	Normal	Normal
Below $-2$ SD	Moderately underweight	Stunted	Wasted/Moderate acute malnutrition
Below $-3$ SD	Severely underweight	Severely stunted	Severely wasted/Severe acute malnutrition

**Table 2** Classification of nutritional status based on mid upper-arm circumference (MUAC) for children aged 6 months to 5 years

MUAC in cm	Nutritional status
12.5 cm or more	Normal
11.5–12.4 cm	Moderate acute malnutrition or Wasted
Less than 11.5 cm	Severe acute malnutrition or Severely wasted

**Table 3** Recommended criteria for identification of severe acute malnutrition (SAM)

Age	Criteria
6 months to 5 years <sup>#</sup>	<ul style="list-style-type: none"> <li>Weight-for-height/length is less than <math>-3</math> SD and/or</li> <li>Mid-upper arm circumference (MUAC) <math>&lt; 11.5</math> cm and/or</li> <li>Bilateral pitting edema of both feet*</li> </ul>
Less than 6 months**	<ul style="list-style-type: none"> <li>Weight-for-height/length is less than <math>-3</math> SD and/or</li> <li>Bilateral pitting edema of both feet*</li> </ul>

<sup>#</sup>IAP guideline included *severe wasting* as one of the criteria; however, this may be subjective and should be used only when mid-upper arm circumference or weight/height/length measurement is not feasible.

\*Unilateral edema is not an indicator of SAM and there should not be a known cause of edema like nephrotic syndrome, congestive heart failure, etc.

\*\*For children with length less than 49 cm, visible severe wasting is used to identify.

**Moderate acute malnutrition** A child who has WFH SD score between  $-3Z$  and  $-2Z$ , or mid-upper arm circumference of 11.5–12.4 cm and has no bilateral pitting edema is classified as having moderate acute malnutrition.

## How Common is Severe Acute Malnutrition?

Severe acute malnutrition is an important cause of morbidity and death in children. The absolute number of children with SAM is much higher in Asia (13.3 million) than in Africa (5.6 million), although the overall prevalence of SAM in Africa is slightly higher than in Asia. The prevalence of SAM in Asia ranges from 0.8% in Bhutan to 7.7% in Laos (**Fig. 1**). As shown in **Figure 2**, NFHS 2006 data has shown high prevalence of wasting in Madhya Pradesh, Chhattisgarh, Jharkhand, Rajasthan, Bihar, Meghalaya and Odisha.

## Why Acute Malnourished Children Need Early Identification and Treatment?

Malnutrition contributes significantly to under-5 mortality as undernourished children have increased susceptibility to infections and, hence, frequent episodes of illness and longer recovery period. Malnutrition lowers the immunity of the child and increases the risk of infection. At the same time, infection results in loss of appetite, increased nutrient requirements and/or decreased absorption of nutrients consumed, which can further cause malnutrition, leading to a vicious cycle. These frequent illness episodes cause economic loss to the family and nation. Moreover, malnourished children have approximately nine times higher risk of mortality due to common illness like diarrhea, etc. pneumonia as compared to children with normal nutritional status.

## Why Children with Severe Acute Malnutrition Need to be Treated Differently?

A child with SAM has higher risk of mortality due to several physiological changes occurring in these children, which is known as reductive adaptation.

## What is Reductive Adaptation?

The systems slow down and do less work in order to allow survival on limited calories. When a child's carbohydrate intake is insufficient, fat stores are utilized to provide energy. Later protein is mobilized from muscles, skin and gut. Physiological and metabolic changes also take place to conserve energy. These changes take place in an orderly progression, which is

**Figure 1** Reported prevalence of SAM in under-five children in different countries between 1999 and 2007  
Abbreviation: SAM, severe acute malnutrition.

**Figure 2** Nutritional status of under-five children (NFHS-3, 2006)

called reductive adaptation. A child with SAM conserves energy mainly by reducing physical activity and growth; reducing basal metabolism by slowing protein turnover; reducing the functional reserve of organs; slowing the sodium and potassium pumps in cell membranes and reducing their number; and reducing inflammatory and immune responses.

### Consequences of Reductive Adaptation

The functioning of every cell, organ and system is affected and this puts the child in a very fragile state. Following is a brief description of the effects on different organs:

- The liver is less able to make glucose; so there is increased risk of hypoglycemia and hypothermia. In addition, liver is

less able to excrete excess dietary protein and toxins. These changes have implications for feeding. First, long gaps without food must be avoided. This means giving frequent feeds day and night, which is a ready source of glucose. Second, we must limit protein intake to avoid stressing the liver.

- The kidneys are less able to excrete excess fluid and sodium. So, excess fluid and sodium (from feeds or rehydration fluid) can lead to fluid overload.
- The heart is smaller and weaker and has a reduced output. Any excess fluid in the circulation stresses the heart and can lead to death from heart failure. This means that fluid intake must be carefully controlled initially. Also, feeds and rehydration fluid must be low in sodium.

- The gut produces less acid and smaller amounts of enzymes. The intestinal villi are flattened, motility is reduced. These changes cause bacterial colonization of the small bowel, damage of the mucosa and deconjugation of bile acids. So, initially, feeds must be small to avoid exceeding the gut's functional capacity, and the composition of feeds should be such that it can easily be absorbed. Feeds should be *enteral*, *never parenteral*, to reduce the risk of fluid overload. Repair of the gut is also quicker if nutrients are physically present in the lumen.
- During reductive adaptation, sodium leaks into cells due to fewer and slower pumps, leading to excess body sodium. Potassium leaks out of cells and is lost in urine, contributing to electrolyte imbalance, anorexia, fluid retention and heart failure. So, we need to restrict sodium and provide potassium. We must also provide magnesium to help the potassium get into cells.
- Reduction in muscle mass is accompanied by loss of intracellular nutrients and smaller reserves of muscle glycogen.
- Red cell mass is also reduced, liberating iron. Conversion of harmful *free-iron* to ferritin needs glucose and amino acids, and there may not be enough glucose available to put all the iron into safe storage. Free iron promotes the growth of pathogens and the production of free radicals which damage cell membranes. So, during initial feeding, we need to withhold iron, and provide vitamins and minerals to help mop up free radicals.

Median case fatality rate in children with SAM is very high, i.e., approximately 23.5% if these changes are not kept in mind. Reasons for high case fatality are listed in **Box 1**. The case fatality can be brought down to approximately 7–10% by standard case management protocol.

#### BOX 1 Ten reasons for high mortality in severe acute malnutrition

1. Inability to distinguish between acute and rehabilitation phases
2. Excessive use of intravenous fluids
3. Fluid overload due to lack of monitoring during rehydration
4. Use of diuretics for edema
5. Use of albumin for edema
6. Not keeping the child warm and euglycemic
7. Low index of suspicion for infection
8. Early use of diets high in protein and sodium
9. Failure to monitor food intake
10. Early treatment of anemia with oral iron.

### Initial Work-up

Before taking detailed history in a child with SAM, it is important to look for emergency signs. In presence of any of the following emergency signs, immediate emergency treatment should be provided to child before further evaluation.

1. Not breathing/severe respiratory distress
2. Coma/convulsion
3. Shock
4. Severe dehydration.

If there are no emergency signs, obtain history and examination as described in **Table 4** to find out causes (food scarcity, secondary causes), medical complications, and deciding level of treatment. Laboratory tests that should be routinely done on admission include: blood glucose, serum electrolytes, hemoglobin, PCV in children with severe palmar pallor, and screening for infections. Investigations to identify presence of infections include total and differential leukocyte count; urine routine and microscopic examination; chest X-ray; blood culture and urine culture; Mantoux test; and peripheral smear for malarial parasite. Investigations for secondary causes such as HIV, celiac disease, etc., are undertaken as per clinical suspicion.

**Table 4** History and examination of a child with severe or moderate acute malnutrition

History	Examination
<ul style="list-style-type: none"> <li>• Total duration of sickness</li> <li>• Dietary intake of food and fluids</li> <li>• Breastfeeding</li> <li>• Complementary feeds—introduction time, quality, quantity</li> <li>• Loss of appetite</li> <li>• Any contact with tuberculosis</li> <li>• History of measles in the last 3 months</li> <li>• Known HIV infection</li> <li>• Health of parents</li> <li>• Immunization</li> </ul>	<ul style="list-style-type: none"> <li>• Anthropometric measurements (weight, height/length, MUAC)</li> <li>• Temperature</li> <li>• Pulse rate/heart rate</li> <li>• Respiratory rate</li> <li>• Sensorium</li> <li>• Edema</li> <li>• Lymphadenopathy</li> <li>• Signs of dehydration if history of diarrhea</li> <li>• Capillary refill time</li> <li>• Palmar pallor</li> <li>• Eye signs for vitamin A deficiency*</li> <li>• Localized signs of infections (ear, throat, skin, lungs)</li> <li>• Mouth ulcers/oral thrush</li> <li>• Skin changes for dermatosis</li> </ul>
<ul style="list-style-type: none"> <li>• Duration and frequency of common complaints               <ul style="list-style-type: none"> <li>– Diarrhea (watery/bloody),</li> <li>– Vomiting</li> <li>– Fever</li> <li>– Cough</li> </ul> </li> </ul>	<ul style="list-style-type: none"> <li>• Systemic examination—look for hepatosplenomegaly, any murmur or deformities, hypertonia (cerebral palsy) or signs of meningeal irritation</li> </ul>

\*One should be very gentle and careful during examination of the eye to prevent the risk of rupture and blindness particularly if the child resists opening of eyes. Abbreviation: MUAC, mid-upper arm circumference.

## MANAGEMENT OF SEVERE ACUTE MALNUTRITION

Two levels of therapeutic treatment are provided, depending on the presence or absence of appetite (as judged by the appetite test) (**Box 2**) and/or medical complications. In the presence of good community-based management, the vast majority (85–90%) of children with SAM may be managed in the community while only a minority, those with poor appetite and/or with medical complications (10–15%) will need facility-based care in a health facility or nutritional rehabilitation centers (NRCs).

### Community Level

Children with SAM, who have good appetite and are free of medical complications, can be managed at home. These children should receive appropriate therapeutic food and routine medicines from a nearby health facility. Mothers give these therapeutic food and medicines at home and attend health facility or nutritional centers weekly for checkups and to receive supplies of therapeutic food.

#### BOX 2 Appetite test

- The test should be conducted in a separate quiet area
- Explain to the mother the purpose of the test and how it will be carried out
- Ask the mother to wash her hands with soap
- The mother should sit comfortably with the child on her lap
- She should offer therapeutic food gently
- She should encourage the child for feeds
- The child must not be forced to take the therapeutic food
- The child should have free access to water to drink while taking therapeutic foods

#### How to interpret the result?

**Pass:** Child eats eagerly;

**Fail:** Child refuses therapeutic food even after persistent encouragement.

**BOX 3** Indications for hospital management in severe acute malnutrition

- Age less than 6 months
- Presence of any emergency signs
- Hypothermia (axillary temperature < 35°C)
- Edema
- Persistent vomiting
- Very weak, apathetic
- Fever (axillary temperature > 39°C)
- Fast breathing, chest in-drawing
- Extensive skin lesions, eye lesions
- Diarrhea with dehydration
- Severe anemia
- Purpura or bleeding tendency
- Evidence of systemic infections or complications.

**Facility Level**

Children with SAM, who have poor appetite and/or medical complications and/or edema are managed in a health facility as inpatients until they fulfill criteria to be shifted to community management program. Children with medical complications (**Box 3**) require facility based management, preferably at a NRC. In addition to these indications, the child whose mother or caregiver is not able to manage at home, or the child who is not improving, or has weight loss while enrolled in community-based program, should also be admitted in a health facility.

World Health Organization (WHO) has recommended 10 steps of management for SAM children with medical complications (**Fig. 3**).

**Step 1: Treat or Prevent Hypoglycemia**

The blood sugar level is considered low when it is less than 3 mmol/L (< 54 mg/dL). The hypoglycemic child is usually hypothermic also. If hypoglycemia is not prevented or detected early they become lethargic, limp and become unconscious. Sweating and pallor may not occur in children with SAM in presence of hypoglycemia. Treatment is as follows:

**Conscious child** If child is asymptomatic and conscious, give 10% glucose or sucrose 50 mL oral by nasogastric (NG) tube

immediately. This should be followed by starter diet (F-75) every 30 min for first 2 hours and thereafter at 2-hourly intervals.

**Unconsciousness, lethargy, convulsions** Give 10% glucose 5 mL/kg intravenously followed by 10% glucose/sucrose 50 mL orally. Start feeding F-75 diet half an hour after giving glucose and then give it every half an hour during the first 2 hours. Blood sugar should be repeated after 30 min. In case it is still low, repeat 10% glucose bolus.

**Step 2: Treat or Prevent Hypothermia**

Hypothermia is low body temperature defined as axillary temperature below 35°C or rectal temperature below 35.5°C. In children with SAM, less heat is generated due to low basal metabolic rate and inactivity and they are at high risk of losing heat due to lack of insulating fat and higher surface area per kg body weight. Both hypothermia and hypoglycemia are signs that the child has a serious systemic infection and so all children with hypothermia should be treated for hypoglycemia and infection also. If the child is hypothermic, active rewarming is required to raise temperature. Use one of the following rewarming techniques:

- Have the mother hold the child with skin to skin contact (kangaroo technique), and cover both of them. Keep the child's head covered.
- Provide heat with an overhead warmer or radiant heater. Do not point the heater directly at the child and avoid contact with hot water bottles, so as to prevent burns.

In case of severe hypothermia (rectal temperature < 32°C), give warm humidified oxygen and 10% glucose bolus. Use radiant warmer and do slow rewarming to avoid disequilibrium.

**Step 3: Treat or Prevent Dehydration**

Misdiagnosis and inappropriate treatment for dehydration is the commonest cause of death in a child with SAM. Malnutrition results in slowing down of sodium-potassium pump which makes children sensitive to sodium overload. At the same time, total sodium is high in malnourished children. Once excess sodium has been given, either because of a mistaken diagnosis or overenthusiastic rehydration in the emergency department, it is very difficult to get the sodium out of the child. When the starter

	Steps	Stabilization		Phase
		Days 1–2	Days 3–7	Rehabilitation week 2–6
1	Treat/Prevent hypoglycemia	=====		
2	Treat/Prevent hypothermia	=====		
3	Treat/Prevent dehydration	=====		
4	Correct electrolyte imbalance	=====		
5	Treat/Prevent infection	=====		
6	Correct micronutrient deficiencies	=====	No iron =====	With iron =====
7	Start cautious feeding	=====		
8	Achieve catch-up growth			=====
9	Provide sensory stimulation and emotional support	=====		
10	Prepare for discharge and follow-up			=====

**Figure 3** Ten steps for management of children with severe acute malnutrition (SAM)

(F-75) diet is given and cell membrane function starts returning to normal, large amounts of sodium come out of the cells (and potassium enters the cells). So, deterioration in general condition may occur on day 2–3.

It is difficult to determine dehydration status in a child with SAM correctly, as the usual signs of dehydration (such as lethargy, sunken eyes) may be present in these children all of the time, whether dehydrated or not. For diagnosis of dehydration, there should be definite history of diarrhea and history of a recent change in the child's eyes. Even very experienced clinicians may misdiagnose dehydration. For this reason, one should closely monitor and always be prepared to revise the diagnosis of dehydration. Treatment of dehydration in children with SAM without shock consists of fluid administration orally or through NG tube. Every 30 min, 5 mL/kg body weight of rehydration solution should be given during first 2 hours and then 5–10 mL/kg every alternate hour for up to 10 hours. The amount offered in this range should be based on the child's willingness to drink and the amount of ongoing losses in the stool. Starter (F-75) diet is given every hour during this period until the child is rehydrated. All children during rehydration should be closely monitored with weight, pulse rate, respiratory rate and signs of overhydration (**Flow chart 1**).

WHO recommended rehydration solution for malnourished children (ReSoMal) is not available commercially. ReSoMal may be prepared from low osmolarity ORS as described in **Table 5**. However if preparation is not possible, rehydrate with low osmolarity ORS and additional potassium supplements. Intravenous fluids should not be used to treat dehydration except in case of shock with lethargy or unconsciousness. Since the degree of dehydration cannot be determined by clinical signs and too much fluid can cause heart failure, it is very important that fluids are not

**Table 5** Composition of ReSoMAL (Rehydration solution for malnourished children)

Component	Amount (mmol/L)
Glucose	125
Sodium	45

Zinc	0.3
Copper	0.045
Osmolarity	300

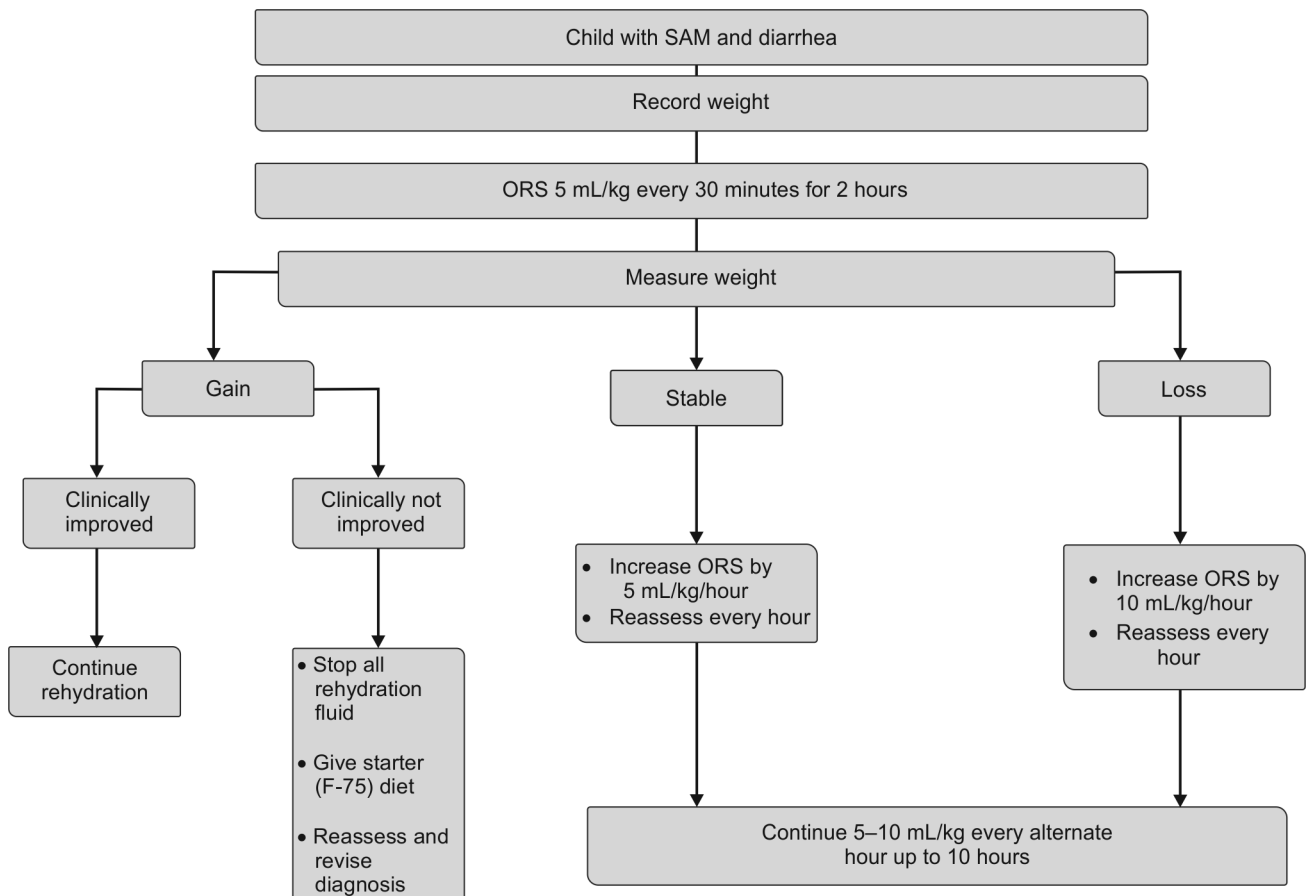

ReSoMAL may be prepared with low osmolarity ORS by dissolving one packet (1L) in 2,000 mL and addition of 50 g of sugar and 40 mL of mineral mix solution.

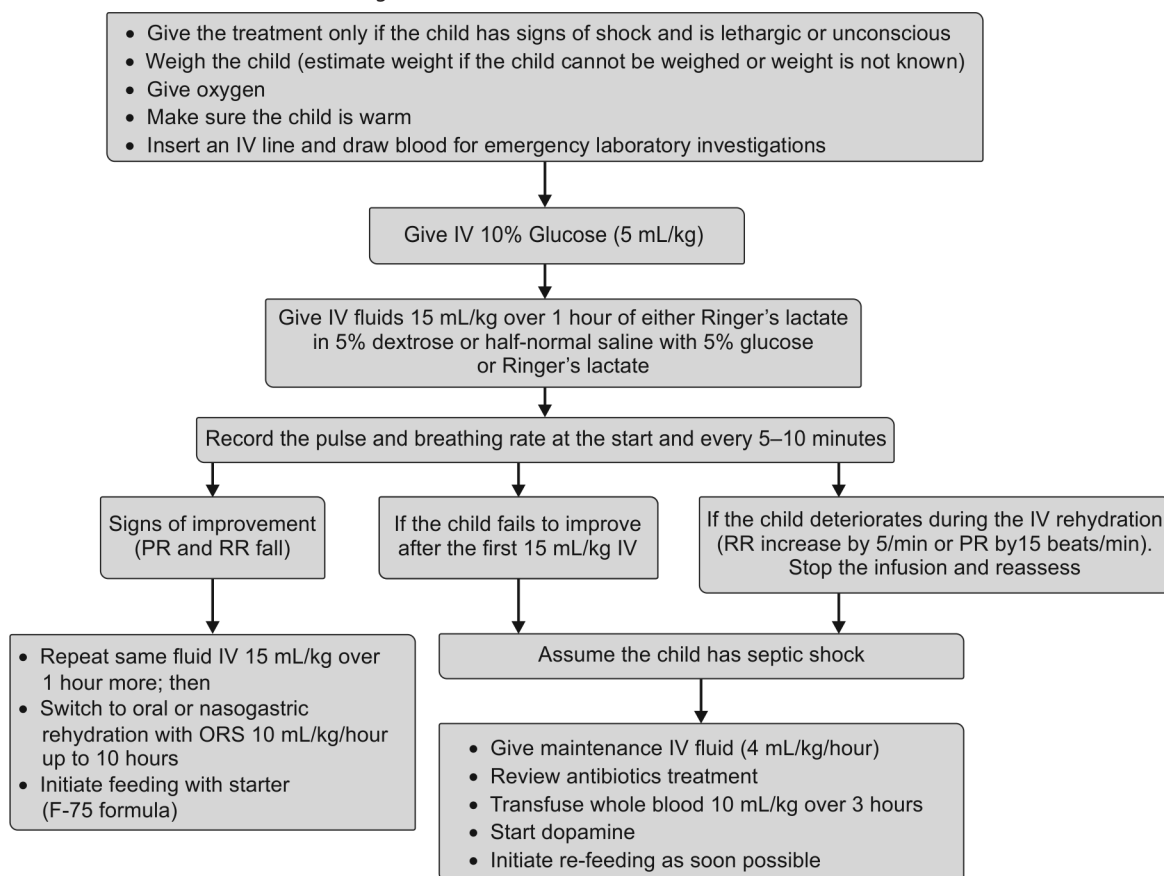

to forced on the child. The child with SAM is considered to be in shock if he or she has cold hands with slow capillary refill (longer than 3 sec) and weak and fast pulse (for a child between 2 months and 12 months of age, a fast pulse is 160 beats or more per minute.; between 12 months and 5 years of age, a fast pulse is 140 beats or more per minute). The management of shock in children with SAM who are lethargic or unconscious is summarized in **Flow chart 2**.

#### Step 4: Correct Electrolyte Imbalance

All children with SAM should be given potassium (3–4 mEq/kg/day). Also give magnesium sulfate 50% once (0.3 mL/kg) up to a maximum of 2 mL on day 1; thereafter, give magnesium sulfate

**Flow chart 1** Management of dehydration in children with severe acute malnutrition (SAM)

**Flow chart 2** Management of shock in children with severe acute malnutrition (SAM)

Abbreviations: PR, pulse rate; RR, respiratory rate.

0.2–0.3 mL/kg/day orally with feeds. Magnesium is essential for potassium to enter the cells and be retained. Children with SAM already have excess sodium in their cells; so sodium intake should be restricted. Both potassium and magnesium supplementation should be continued for at least 2 weeks.

### Step 5: Give Antibiotics

Majority of SAM children have hidden infection. In spite of infection, the usual signs of infection, such as fever, are often absent. Hence, all children with SAM should be given broad spectrum antibiotics. Give the first dose of antibiotics as soon as possible while other initial treatments are going on. Uncomplicated children should receive oral amoxicillin while admitted children should receive combination of ampicillin or third generation cephalosporin with aminoglycosides.

### Step 6: Give Micronutrients

Give oral vitamin A in a single dose to all children with SAM unless there is evidence of receiving vitamin A dose in the last 1 month. Children with clinical signs should be given 3 doses on days 1, 2 and 14. Give other micronutrient supplements daily for at least 2 weeks unless the child is receiving therapeutic food containing these micronutrients: multivitamin supplement (should contain vitamins A, C, D, E and B<sub>12</sub>) twice RDA; folic acid: 5 mg on day 1, then 1 mg/day; elemental zinc: 2 mg/kg/day; and copper: 0.3 mg/kg/day.

### Step 7: Start Cautious Feeding

Children with SAM cannot tolerate usual amounts of protein, sodium or high amounts of fat initially. They may die if given too much protein or sodium. But they need glucose, so they must

be given a diet that is low in protein and sodium and high in carbohydrates. The starter (F-75) diet is designed to fulfill these requirements (**Table 6**).

Give starter (F-75) diet 130 mL/kg (100 mL/kg in case of edema) divided in 12 feeds, i.e., every 2 hours including night. If the child is hypoglycemic, one-fourth of the 2-hourly feed should be given every half hour for the first 2 hours until the child's blood glucose is normal. After the first day, increase the volume per feed gradually so that the child's system is not overloaded. The child will gradually be able to take larger, less frequent feeds (every 3 hours or every 4 hours). If commercially prepared F-75 is not available, starter (F-75) diet may be prepared locally as described in **Table 7**. Most of the children with SAM are able to accept oral feeding. However,

**Table 6** Composition of WHO recommended F-75 and F-100 diets

Constituents	Amount per 100 mL	
	F-75	F-100
Energy (calories)	75	100
Protein (g)	0.9	2.9
Lactose (g)	1.3	3.0
Potassium (mmol)	3.6	5.9
Sodium (mmol)	0.6	1.9
Magnesium (mmol)	0.43	0.73
Zinc (mg)	2.0	2.3
Copper (mg)	0.25	0.25
Osmolality (mOsmol/L)	333	419

**Table 7** Preparation of Starter/Catch up diet locally for treatment of severe acute malnutrition

S. No.	Contents	Starter (F-75 diet) (cereal-based)	Starter (F-75 diet) (noncereal-based)	Catch-up (F-100) diet (cereal-based) Amount for 100 mL	Catch-up (F-100) diet (noncereal-based) Amount for 100 mL
1.	Cow's milk/full cream dairy milk	30 mL	30 mL	75 mL	90 mL
2.	Sugar	7 g	10 g	2.5 g	7.5 g
3.	Vegetable oil	3.5 g	-	2 g	2 g
4.	Puffed rice	2 g	2 g	7 g	-
5.	Water to make	100 mL	100 mL	100 mL	100 mL
	<i>Composition</i>	<i>Amount</i>	<i>Amount</i>	<i>Amount</i>	<i>Amount</i>
1.	Energy (kcal/100 mL)	75	77	100	100
2.	Protein (g/100 mL)	1.1	0.9	2.9	2.9
3.	Lactose (g/100 mL)	1.2	1.2	3	4.2

remember that they have weak muscles and swallow slowly. Encourage breastfeeding on demand between therapeutic feeds. It may be necessary to use an NG tube if the child is very weak; has mouth ulcers that prevent drinking; or cannot take enough F-75 diet by mouth (is not able to finish 80% of the amount offered on 2–3 consecutive feeds).

### Step 8: Achieve Catch-up Growth

F-100 diet is used to rebuild wasted tissues after stabilization which provides 100 kcal energy and 2.9 g protein per 100 mL. Following signs indicate readiness to move from F-75 to F-100:

- Return of appetite (easily finishes 4-hourly F-75 diet)
- No episodes of hypoglycemia or hypothermia
- Edema starts disappearing.

Transition usually takes 3 days, during which catch-up (F-100) diet should be given according to the schedule given in **Box 4**. The goal is to achieve a calorie intake of 150–220 kcal/kg/d and protein of 4–6 g/kg/day.

#### BOX 4 Schedule of transition from F-75 to F-100

*First 48 hours (2 days):* Give Catch-up (F-100) diet every 4 hours in the same amount as you last gave starter (F-75) diet.

*On the 3rd day:* Increase each feed by 10 mL as long as the child is finishing feeds up to a maximum of 220 mL/kg. If the child does not finish a feed, offer the same amount at the next feed. If the child is breastfeeding, encourage the mother to breastfeed between feeds of F-100 diets. Remember F-100 diet is given in the range of 150–220 mL/kg according to current weight of the child.

**Monitoring** Weight is recorded daily to monitor the progress:

- Good weight gain: 10 g/kg/day or more
- Moderate weight gain: 5–10 g/kg/day
- Poor weight gain: less than 5 g/kg/day

A child is failing to respond if he or she does not improve initially; or gains weight but then levels off or deteriorates. Child is also said to fail treatment if there is: (a) failure to regain appetite by day 4; (b) failure to lose edema by day 4; or (c) edema still present on day 10. Failure to gain at least 5 g/kg/day for 3 successive days after feeding freely on catch-up (F-100) diet is a matter of concern and needs evaluation.

### Step 9: Sensory Stimulation

Due to lack of interaction and play, children with SAM have delayed mental and behavioral development. Play therapy is intended to develop language and motor skills aided by simple, inexpensive toys. It should take place in a loving, relaxed and

stimulating environment. Physical activity should be stimulated as soon as the child is well. Mothers should be taught to play with their children using simple, homemade toys. It is important to play with each child individually for at least 15–30 min/day, in addition to informal group play.

### Step 10: Prepare for Discharge and Follow-up

WHO (2009) guidelines had recommended 15% weight gain as one of the criteria for discharge but the current evidence fails to support it as it results in the more severely malnourished children getting the shortest duration of treatment and being discharged when still malnourished. According to recent (2013) WHO recommendation, children with SAM should be discharged when either weight-for-height or length is more than or equal to –2 Z-score or mid-upper arm circumference is more than or equal to 125 mm (depending upon admission criteria) criteria and they have had no edema for at least 2 weeks.

Whenever there is community-based program available, children may be shifted after stabilization at the facility, i.e., fulfilling following criteria:

- Appetite returned to normal (eats at least 75% of therapeutic food)
- Medical complications resolved
- No edema
- Satisfactory weight gain (at least 5 g/kg/day) for 3 consecutive days.

The decision to transfer children from inpatient to outpatient care should be determined by their clinical condition and not on the basis of specific anthropometric outcomes, such as a specific mid-upper arm circumference or weight-for-height/length Z-score. Before discharge from facility immunization should be updated and treatment for helminthic infections should be given as 200 mg albendazole for children aged 12–23 months; and 400 mg for older children.

### Criteria Related to Mother or Caregiver

- Knows how to prepare appropriate foods and feed the child
- Knows how to make toys and play with the child
- Knows how to give treatment at home for diarrhea, fever and acute respiratory infection
- Knows how to recognize danger signs for which they should seek medical assistance
- Follow-up plan has been explained to them.

**Follow-up plan** Before discharge, the need to follow-up and the plan should be explained to the mother and family. They should be followed every 15 days, up to 2 months (four follow-up visits)

and then monthly until WFH SD score reaches  $-1$  SD or above. At each follow-up visit, the child should be examined for any medical complications; the child should be weighed. In case there is no weight gain or weight loss, look for the cause; and the mother should be asked about the child's recent health, feeding practices and play activities.

### Ready-to-Use Therapeutic Food

Based on experiences from several countries; WHO and UNICEF have recommended use of ready-to-use therapeutic food (RUTF) for management of children with SAM without complications. These children are managed under an outpatient therapeutic program where they are provided with a high energy *therapeutic food*. RUTF is a kind of therapeutic food which is energy dense and at least 50% proteins obtained from milk products. Conventionally, the ingredients used in the production of RUTF are milk powder, vegetable oil, peanuts, sugar, minerals and vitamins. Shelled and roasted groundnuts are broken to smaller particle size in a grinder. Skimmed milk powder, the ground peanuts, vegetable oil, powdered sugar and the minerals and vitamins are then amalgamated in a mixer and the paste is further homogenized to reduce particle size ( $< 200 \mu\text{m}$ ). They can be easily and safely administered to children with SAM of more than 6 months of age by the caregiver. The absence of water in RUTF gives them protection against bacterial contamination and the ease of storage at home even without refrigeration. RUTF is consumed with plenty of water every 2–3 hourly in an amount described in **Table 8**. While the child is on therapeutic food, breastfeeding should be continued. If the child desires and there is no diarrhea, then even other home-cooked foods may be given.

**Table 8** Amount of ready-to-use therapeutic food (RUTF)

Weight (kg)	Amount of RUTF (g/day)
3–4.9	105–130
5–6.9	200–260
7–9.9	260–400
10–14.9	400–460

Although the efficacy of RUTF has been shown in several African countries and other regions, there are concerns regarding its misuse. Since the administrative system is porous and there is a chance of commercial exploitation and misuse of RUTF, so it is essential to ensure the availability and utilization of RUTF to the target population only. At present, RUTF is not approved for its use in SAM children by the Government of India.

### IN A NUTSHELL

1. Presence of severe acute malnutrition (SAM) increases risk of mortality in common illnesses like diarrhea, pneumonia by approximately 8–9 times as compared to children without malnutrition.
2. Due to reductive adaptation, children with SAM are at high risk of hypoglycemia, hypothermia, electrolyte imbalance, infections and heart failure.
3. All SAM children with loss of appetite and medical complications should be treated in a health facility while those without complications may be treated in community.
4. WHO has recommended 10 steps of management for children with SAM. Early identification, special therapeutic diet (F-75/F-100), broad-spectrum antibiotic, sodium restriction and supplementation of potassium and magnesium are integral parts of management.
5. In children with SAM, all the signs of dehydration are unreliable. So rehydration should be slow under close monitoring. IV fluids should not be used to treat dehydration in children with SAM (except in case of shock).
6. Structured play therapy improves outcome in children with SAM.

## Chapter 22.9

### Vitamin A

Neetu Sharma, Piyush Gupta

Vitamin A is a subgroup of retinoids exhibiting the biological activity of retinol. Naturally occurring retinoids include retinol (vitamin A alcohol), retinyl palmitate (vitamin A ester), retinal (vitamin A aldehyde) and retinoic acid (vitamin A acid). Retinoic acid is the most active form of vitamin. Vitamin A from the diet is ingested as carotene (from plant sources) and retinyl esters (from animal sources). Beta-carotene (provitamin A) yields the highest amount of retinol. The absorption of dietary beta-carotenes varies according to the source, and is generally assumed to be 50%. Absorbed vitamin A is stored in liver as retinyl palmitate. Zinc is required for mobilization of retinyl palmitate to free retinol. The general term vitamin A is usually used for retinol.

#### PHYSIOLOGY

Body obtains vitamin A in two forms, i.e., preformed vitamin A (ester) and provitamin A (carotenoids). Retinyl esters are hydrolyzed to retinol by pancreatic triglyceride lipase and the intestinal brush border enzyme phospholipase before being taken in by the enterocytes by a saturable carrier-mediated process. Carotenoids are disintegrated into retinol by carotene cleavage enzyme dioxxygenase in the small intestinal lumen before being taken up in the enterocytes by passive diffusion. Retinol is then re-esterified with long chain fatty acids (mainly palmitate) in the enterocytes after absorption. In enterocytes, retinol is bound to cellular retinol-binding protein type II (CRBP-II) that facilitates retinol esterification by the enzyme lecithin: retinol acyltransferase (LRAT). Most of the retinyl palmitate (esters) thus produced are incorporated into chylomicrons, and secreted from the enterocytes into the intestinal lymph and moved to liver and other tissues for storage. A sizeable chunk of absorbed vitamin A is secreted into portal circulation as unesterified retinol. This pathway holds importance in situations where secretion of chylomicrons is affected, as in abetalipoproteinemia. Extra-hepatic uptake is also important to make retinyl esters and carotenoids available to tissues, such as mammary tissue, bone marrow, adipose tissue, and spleen bone marrow, peripheral blood cells, spleen, skeletal muscle and kidney. After hydrolysis of retinyl esters in hepatocytes, unesterified retinol binds to retinol-binding protein (RBP), and is sent from the liver to tissues as the *holo*-RBP complex. Most of the plasma RBP is affiliated with transthyretin (TTR) and this complex provides the retinol as well as thyroid hormones to the tissue. RBP is crucial for mobilization of hepatic retinol into plasma, and for cellular uptake of retinol in the retina. In addition, about 50–80% of unesterified retinol in hepatocytes is transferred to perisinusoidal stellate cell for storage where it is packed in cytoplasmic lipid droplets. This huge storage of retinyl esters in stellate cells acts as a reserve of vitamin A for few weeks or months, ensures a steady blood plasma retinol level despite fluctuations in daily intake of vitamin A.

#### FUNCTION

Vitamin A and its metabolites play several critical roles in body physiology. These effects are mediated via retinoic acid which is an important signaling molecule acting as a ligand for specific nuclear transcription factors. Vitamin A is vital for vision. Apart from its role in vision, vitamin A is necessary for regulation of many genes involved in cell division and differentiation. Many

physiologic processes involving the fetal growth and development, reproduction, gastrointestinal and respiratory function and immunity are dependent on vitamin A. Carotenoids, precursors of vitamin A are also important antioxidant defenses.

#### Vision

Vitamin A works in the retina, through its aldehyde (retinal) form which is the prosthetic group on visual proteins rhodopsin and iodopsin. During low-intensity light, 11-cis-retinal in rhodopsin is converted to all-transretinal which generates an electrical signal transmitted via the optic nerve to brain, resulting in night (low-intensity light) vision. Thus, deficiency of vitamin A results in night blindness. Secondly, vitamin A is also essential to maintain the conjunctival mucosa and the corneal stroma via conjunctival epithelial cell ribonucleic acid (RNA) and glycoprotein synthesis.

#### Resistance to Infections

Vitamin A is commonly known as the anti-infective vitamin. The two prime functions responsible for the prevention of diseases are the effect on the immune system and on epithelial integrity. Both humoral immunity and cell-mediated immunity are depressed by deficiency of vitamin A. The principal effects seem to be a consequence of impaired growth and differentiation of myeloid tissues as retinoic acid is essential for development and differentiation of white blood cells, especially activation of T-lymphocytes. Vitamin A deficiency (VAD) has been shown to increase the frequency and severity of many infectious diseases. Vitamin A supplementation has been found to reduce mortality from measles and diarrhea.

#### Epithelial Cell Integrity

Vitamin A is essential for the integrity and function of skin and mucosal cells of the respiratory airways, digestive tract and urinary tract that acts as a barrier and builds the body's first line of defense against infection. In hypovitaminosis A, mucus secretion decreases, mucosa atrophies goblet cells are lost, and keratinization of skin occurs. Destruction of this first line defense leads to the invasion by microorganism and increased severity of infection.

#### Growth and Development

In fetal development, retinoic acid is required for the development and formation of the heart, limb, eyes and ears. It may have a role in regulation of expression of the gene for growth hormone. Retinoic acid is present in abundance in the developing brain and found to be associated with synaptic plasticity of the hippocampus. Thus, it has a role in the spatial and relational memory and maturation of learned behaviors.

#### Antineoplastic Activity

Vitamin A has a role in cancers of mouth, skin, bladder, lung, prostate and breast. It is used as a therapeutic agent in certain premalignant lesions, such as oral leukoplakia, xeroderma pigmentosum and cervical dysplasia.

#### Others

Vitamin A is required for normal functioning of osteoblasts and osteoclasts. Sperm production requires normal level of vitamin. Vitamin A helps in normal stem cell differentiation as well as in mobilization of iron from storage sites to the developing red blood cell. Change in retinoic acid level results in several abnormalities, like absence of posterior hindbrain, abnormal dorsoventral patterning of the spinal cord, and is found to be involved in CNS disorders like Alzheimer's disease, schizophrenia, depression and sleep disorders.

## SOURCES

Breastmilk fulfills the needs of vitamin A entirely for the first 6 months of life. It continues to be an important source (38–75% of requirement) depending on mother's vitamin A status and volume of the breastmilk consumed, up to 2 years of age. Preformed vitamin A (retinol) is abundant in fish liver oils, liver, dairy products and egg yolk. Vegetarian sources of vitamin A include green leafy vegetables, and yellow fruits and vegetables, such as carrots, papaya, tomatoes, sweet potatoes, mango, broccoli and spinach. Liver is the richest dietary source. Some processed foods and infant formulas are now fortified with preformed vitamin A. Dehydroretinol (vitamin A<sub>2</sub>), with 40% biological activity of retinol, is found only in freshwater fish.

## RECOMMENDED DAILY ALLOWANCE

Infants (0–12 months): 350 µg; children (1–6 years): 400 µg; children (7–9 years): 600 µg; adolescents and adults: 600 µg; pregnant women: 800 µg; lactating women: 950 µg. All these values are in terms of retinol equivalents (RE) (ICMR, 2011). If carotenes are the sources, the RDA in terms of RE is multiplied by 8 assuming a 1:8 conversion efficiency. It is recommended that minimum 50% of RE should be derived from animal sources to ensure adequacy in vulnerable groups.

1 µg of retinol = 3.33 international units (IU) of vitamin A

1 IU = 0.3 µg of retinol = 0.6 µg of β-carotene = 1.2 µg of other carotenes.

60 g of retinol = 110 mg of retinyl palmitate = 69 mg retinyl acetate = 2 lac IU of vitamin A.

## VITAMIN A DEFICIENCY

Vitamin A deficiency of sufficient duration or severity can lead to xerophthalmia, childhood blindness, anemia, decrease host resistance to infection and increased risk of mortality in under-five children. Subclinical VAD is a severely significant problem in preschool children, while overt VAD is rampant in pregnant women in India.

### Indicators of VAD

Clinically, presence of night blindness is used as the best indicator for VAD. Serum retinol of less than 0.70 µmol/L is used to identify those at risk for biochemical VAD. However, the deficiency problem is overestimated if we do not consider coexisting deficiency of iron, zinc and protein; or take infections into account. Iron deficiency reduces serum retinol levels. Zinc affects metabolism by influencing absorption, transport and utilization. Protein is needed to mobilize liver reserves into blood. A child with severe acute malnutrition will thus have lower serum retinol level. Serum retinol concentrations can be lowered up to 25% by infections, so C-reactive protein should be estimated while assessing serum retinol levels. Serum retinol can be measured by high-pressure liquid chromatography (HPLC), fluorescence or ultraviolet (UV) spectrophotometry in dried blood spots. HPLC is the method of choice, due to its high sensitivity and specificity. Prevalence cut-offs to define significance of VAD in a given population are already detailed in Chapter 22.5.

### Causes of Deficiency

Vitamin A is not synthesized within the body, and needs to be supplied by external sources. Deficiency can occur secondary to defective absorption, altered metabolism, decreased ingestion or increased requirement. While a child's liver can store vitamin A for only few weeks, the same can be stored in adult liver for a year or so. VAD may begin in early neonatal period with discarding of colostrums which is rich in vitamin A. Inadequate breastfeeding adds further to the deficiency. Vegetarians run the risk of having

deficiency as fruits and vegetables, compared with animal sources and fortified foods, provide proportionately insufficient amount of vitamin A. As the beta-carotene : retinol ratio for fruits and vegetables is 12:1 and 26:1, respectively, only 20% of RDA in 4–8 year-old is provided by a 70 g serving of dark-green leafy vegetables. Thus, one has to eat 350 g of leafy vegetables per day to fulfill the RDA requirement, which is difficult in practice. Severe malnutrition is an important cause of deficiency as it leads to impaired synthesis of retinol transport protein. The requirement of vitamin A is increased in preterms, and during infections (measles, respiratory tract infections). Coexisting infection and VAD result in decreased appetite, reduced absorption, excessive metabolism and increased excretion of vitamin A. Moreover, provitamin A is fat-soluble and its absorption depends on the presence of adequate lipid and protein in the diet. Chronic diarrhea, malabsorptive states and chronic liver disease, therefore, cause significant VAD. Zinc deficiency may also increase the risk of VAD.

## Clinical Features

### Subclinical Deficiency

Respiratory system, urinary tract, intestinal epithelium and immune system are affected before the deficiency manifests clinically. Subclinical VAD contributes to an increased severity of certain infections and an increased risk of infection-related mortality. Long-standing deficiency causes several changes and eye tends to be the main victim.

### Xerophthalmia

Defective dark adaptation is the most characteristic early clinical feature, resulting in night blindness. Children in 6–36 months of age are mostly affected.

*Xerosis of the conjunctiva* is usually the first clinical sign. Palpebral conjunctiva loses its sheen and wetness. Wrinkling appears in the conjunctiva which can be appreciated as conjunctival folds when the child moves the eye ball towards the opposite side. It is because the normal lacrimal and mucus-secreting epithelium are replaced by a keratinized epithelium (**Fig. 1**).

*Bitot's spots* are the most characteristic feature of xerophthalmia and appear next as triangular areas on the temporal aspects of junction of cornea with sclera. The spots are made up of heaped up dry masses of conjunctival epithelium. There may be more than one spot measuring from 1 mm to 5 mm. The spots are whitish grey, look dry, non-reflective, and may have embedded wrinkles (**Fig. 2**). These are present bilaterally and associated with a muddy conjunctiva. The spots may be stained black, if the mother has applied kohl (kajal) in the eyes of the infant.

*Corneal xerosis* cornea dries up as the next step. A dry cornea is susceptible to exposure injury and can get ulcerated easily. Ulcers are pinpoint initially and later coalesce. The ulceration spreads to involve most of the cornea. This stage is known as *keratomalacia* and is a forerunner to corneal perforation (**Fig. 3**).

*Blindness* Aqueous humor and iris prolapse out, that ultimately results in corneal blindness. Corneal xerosis is reversible while keratomalacia is irreversible. It results in corneal scarring (**Fig. 4**). On funduscopy, pale yellow spots can be visualized near the course of retinal vessels and also in the periphery.

The sequence of changes described above remains the same, though the rate of progression may be acute, subacute or chronic. WHO classification for ophthalmic manifestations of VAD is tabulated in **Table 1**.

Besides ophthalmic changes, other signs that may appear are excessive deposition of periosteal bone secondary to reduced osteoclastic activity, anemia, recurrent infections as diarrhea, pneumonia, dry skin, dry hair, pruritus and broken fingernails.

**Figure 1** Conjunctival xerosis

**Figure 2** Bitot's spots

**Figure 3** Corneal ulceration

**Figure 4** Corneal scarring

**Table 1** WHO classification of xerophthalmia

<i>Primary signs</i>		<i>Secondary signs</i>	
X1A	Conjunctival xerosis	XN	Night blindness
X1B	Bitot's spots	XF	Fundal changes
X2	Corneal xerosis	XS	Corneal scarring
X3A	Corneal ulceration (< 1/3 of cornea)		
X3B	Corneal ulceration (> 1/3 of cornea)		

## VITAMIN A SUPPLEMENTATION AND CHILD MORTALITY

Vitamin A supplementation has been linked with 23% reduction in child mortality in several trials in developing nations. However, these claims have been challenged. In north India, VAD (retinol < 0.70  $\mu\text{mol/L}$ ) is common in preschool children and 2–3% die at ages 1.0–6.0 years. A large [DEVTA (Deworming and Enhanced

Vitamin A)] trial in preschool children from 8,338 villages from north India contradicts the expectation from other trials that vitamin A supplementation would reduce child mortality by 20–30%, but cannot rule out some modest effect. Meta-analysis of DEVTA plus eight previous randomized trials of supplementation (in various different populations) yielded a weighted average mortality reduction of 11% (95% CI 5–16).

## TREATMENT OF VITAMIN A DEFICIENCY

Xerophthalmia can progress from conjunctival xerosis to perforation very rapidly, resulting in blindness. Thus, any evidence of VAD should be treated on priority and emergency basis.

### Specific Therapy

Treat all children with clinical signs of VAD as early as possible. Immediately on diagnosis, oral vitamin A is administered in a dose of 50,000, 1 lac and 2 lac international units in children aged less than 6 months, 6–12 months and more than 1 year, respectively. The same dose is repeated the next day and 2 weeks later. Parenteral

water-soluble vitamin A administration is recommended (in half the doses suggested above) in children with impaired oral intake, persistent vomiting and severe malabsorption. Oil-based injections should not be used to treat xerophthalmia. Administer vitamin A immediately as per schedule (**Box 1**).

#### BOX 1 Treatment schedule for xerophthalmia

Three doses of vitamin A are given as follows: first dose immediately on diagnosis, second dose 24 hours later and the third dose 1–4 weeks later in an age-specific schedule as shown below:

< 6 months	50,000 units
6–12 months	1 lac units
> 12 months	2 lac units

Vitamin A is available in the form of a syrup (one lac units per mL) or capsule (one lac units per capsule).

Source: Vitamin A supplements. WHO/UNICEF/IVACG task force, WHO, 1997.

### Local Treatment

Antibiotics drops or ointment should be instilled three times a day to prevent secondary infection in the event of presence of corneal ulcer. Padding the eye in such cases prevents dehydration and further corneal exposure. Padding also enhances epithelial healing and reduces pain and photophobia. Mydriatics are necessary; usually atropine drops 1% or ointment is applied once a day.

### PREVENTION AND CONTROL

Vitamin A deficiency in affected populations can be curtailed via three types of community interventions: (a) improving the availability and consumption of vitamin A by dietary diversification and to strengthen the general nutritional standing of the population; (b) food fortification; and (c) periodic mega-dose vitamin A supplementation to preschool children and during pregnancy. These approaches should be seen as complementary to each other.

#### Promoting Consumption of Vitamin A Rich Food

- Encourage regular intake of vitamin A-rich foods by pregnant and lactating mothers and by under-5 children.
- Education to be imparted to mothers attending the antenatal clinic, immunization clinic and Integrated Child Development Services (ICDS) about the importance of preventing VAD.
- Encourage breastfeeding. In particular, rectify the malpractice of discarding colostrums.
- Promote intake of locally available carotene rich foods, i.e., green leafy vegetables and yellow and orange vegetables and fruits like pumpkins, carrots, papayas, mangoes and oranges, along with cereals and pulses. Consumption of milk and milk products, egg and liver must be promoted.
- During economic instabilities, homestead food production can diversify the diet and enhance income. Horticultural interventions including home gardening. Growing of vitamin A-rich foods in the home and in gardens should be promoted to increase the availability of vitamin A-rich foods.
- Nutrition education for dietary diversification. And awareness about consumption of vitamin A-rich foods should be created.
- Nutritional supplementation.
- Provision of safe drinking water and sanitation.

#### Selective Fortification for Risk Areas and Special Groups

In cases where dietary quality cannot be enhanced by food variety, fortification of staple food with vitamin A is a viable and cost-effective intervention. What matters significantly in the fortification process is the compatibility of the food, stability of

vitamin A in the food all through the marketing process and the cost of fortification for each food. Needless to mention that the choice of suitable food for fortification differs from country to country, and can range from refined sugar to edible vegetable oils and fats, from grains like wheat and rice to maize flours, from condiments and seasonings to powdered and liquid milk. Two other issues that need extra attention are packaging and cooking. Since sunlight is harmful for vitamin A, tin containers can ensure preserving maximum of vitamin A. Compared to frying or boiling, pressure cooking preserves more vitamin A nonetheless, in general 65–85% vitamins are preserved irrespective of cooking method.

#### Administering Massive Doses of Vitamin A

A periodic delivery of high-potency supplements, i.e., 2 lac IU of vitamin A to the children up to 5 years of age and half of this dose to infants of 6–11 months of age is the most prevalent practice in most high risk countries to control VAD. In many of these high risk countries, as per the WHO policy, mothers are given this vitamin A supplement as 2 lac IU orally within 6 weeks post-delivery in order to enhance the breastmilk content of vitamin A.

*Prophylactic vitamin A to healthy children* Prophylactic vitamin A (one dose of 1 lac units of vitamin A along with measles vaccine at 9 months followed by four more doses of 2 lac IU each at 18, 24, 30 and 36 months) may be administered in areas with high prevalence of VAD. This practice has been shown to reduce the risks of xerophthalmia by 90% and mortality by 23–30% in young children, however, the effect on increasing the serum retinol concentration is modest. Prophylactic mega dose administration of vitamin A is primarily advocated because of the claim of 23% reduction in childhood mortality. However, benefits on this scale have been found only in areas with rudimentary health care facilities where clinical deficiency is common, and there is substantial heterogeneity, especially with inclusion of all trials. There is an urgent need for adopting a targeted rather than universal prophylactic mega dose vitamin A supplementation in preschool children. This approach is justified on the basis of currently available evidence documenting a substantial decline in VAD prevalence, substantial heterogeneity and uncertainty about mortality effects in present era with improved health-care, and resource constraints with competing priorities.

*Prophylactic vitamin A to sick children* Infants and young children suffering from diarrhea, measles or ARI should be encouraged to consume vitamin A-rich foods and administered an additional dose of vitamin A (**Table 2**). Children suffering from measles and severe malnutrition should be administered oral vitamin A (1 and 2 lac IU each for < 1 year > 1 year olds respectively), on two consecutive days. Those with persistent diarrhea and other prolonged febrile conditions are given one dose in each episode.

*Vitamin A during pregnancy and in neonates* Relatively small increased needs for vitamin A during pregnancy should be met through diet or through a supplement not exceeding 10,000 IU daily throughout pregnancy. Where VAD is endemic in under-fives and maternal diets are low in vitamin A content, administer either a daily 10,000 IU daily supplement at any time during pregnancy, or weekly supplementation 25,000 IU. A single dose more than 25,000 IU is not advisable between day 15 and day 60 following conception.

Breastfed neonates do not need vitamin A supplement in the first 6 months.

The above-mentioned three strategies are considered complementary: hence need to be combined. Besides, other approaches that can also play a vital role in curtailing VAD include strategies for advocating breastfeeding, enhanced vaccine coverage particularly against measles, family planning measure for birth gaps and oral rehydration therapy to cure diarrhea.

**Table 2** Case management schedule for areas with endemic vitamin A deficiency

Disease	Dosage by mouth	Timing
Measles		
< 12 months	1 lac units	On diagnosis and the next day
> 12 months	2 lac units	On diagnosis and the next day
Severe PEM	Same as above	Second dose only if the condition worsens
Persistent diarrhea	Same as above	One dose for each episode with at least a month interval between doses
Other prolonged febrile conditions	Same as above	One dose for each episode with at least a month interval between doses

Abbreviation: PEM, protein-energy malnutrition.

## HYPERVITAMINOSIS A

Several factors can lead to toxicity from preformed vitamin A such as diets with rich sources of vitamin A (liver of certain animals), supplements like cod liver oil, and medicinal form prescribed in various conditions. Levels increase either due to enhanced intestinal absorption of vitamin A or diminished chylomicron clearance. As compared the oil-based retinol preparations, aqueous preparations are 10 times toxic. Since the conversion to the active form of vitamin A is significantly regulated, increased intake of provitamin does not lead to hypervitaminosis. Nonetheless, overconsumption of beta-carotene may result in carotenemia (presenting with yellowish discoloration of skin).

### Clinical Features

Clinical manifestations vary, and so does the dose required for toxicity. Acute toxicity occurs at doses of 25,000 IU/kg of body weight or when adults and children ingest more than 100× and more than 20× the RDA, respectively, over a period of hours or a few days. For liver toxicity, the levels as low as 15,000 IU/day and in renal failure, 4,000 IU/day are reported to be toxic. It gets further sensitive where the body mass is smaller, like in children, where daily intakes of 1,500 IU/kg body weight may cause toxicity.

### Acute Hypervitaminosis A

Acute hypervitaminosis A causes pseudotumor cerebri manifesting as bulging fontanel, vomiting, and irritability in young infants. Older children may complain of diplopia and headache. Papilledema and cranial nerve palsies are rare. Symptoms and signs improve rapidly on withdrawing vitamin A. Acetazolamide, mannitol, or a therapeutic lumbar tap may be needed in severe cases. Other symptoms include nausea, headache, fatigue, loss of appetite, dry skin, desquamation and redness, cerebral edema, drowsiness, dizziness and delirium.

### Chronic Toxicity

Chronic toxicity usually results from intake of medicinal vitamin A over a period of several weeks, where the lowest intake capable of eliciting toxicity differs from person to person. Intake of 4,000 IU/kg of body weight daily for 6–15 months is considered toxic. Chronic hypervitaminosis A results in skin desquamation, alopecia, hepatosplenomegaly, bone swellings and increased intracranial tension. The shaft of long bones may show hyperostosis as synthetic

retinoids are known to change bone metabolism, and an increase in turnover leading to spontaneous bone fracture, osteoporosis, premature epiphyseal closure, hypercalcemia, bone and joints pain, and elevated alkaline phosphatase. Other symptoms of chronic toxicity are hepatosplenomegaly, chronic inflammation of the liver, cirrhosis, dry lips, anorexia, headache, psychiatric changes, conjunctivitis, irritability, mouth ulcers, abnormal softening of the skull bone, changes in consciousness, poor weight gain and hair loss.

Excessive intake of vitamin A is teratogenic during first trimester of pregnancy, and has been linked with central nervous system malformations, other birth defects and spontaneous abortions. An area of emerging concern is the subtoxicity *sans* any clinical signs of toxicity as intake of preformed sources of vitamin A usually tends to exceed the RDA for adults notably in developed nations. Only double the RDA intake of preformed vitamin A has been linked with osteoporosis and hip fracture.

### Management

Diagnosis of toxicity is difficult since serum retinol is not sensitive to toxic level of vitamin A. Even with inconsistent dietary intake of vitamin A, the serum retinol concentrations is maintained within normal range of 1–3 mol/L by homeostatic regulation. Instead fasting retinyl ester concentrations more than 10% of total circulating vitamin A could indicate the toxic level. This occurs as a result of overflowing of extra esters into the blood from already saturated hepatic stellate cells and decreased hepatic uptake of vitamin A. Discontinuation of excessive intakes usually results in complete recovery. Prevention is possible by restricting the intake as per RDA. Caution should be exercised while administering massive doses for prophylaxis and in conditions like pregnancy and liver disease.

### IN A NUTSHELL

1. Vitamin A and its metabolites play critical role in vision, fetal growth and development, reproduction, gastrointestinal and respiratory function and immunity. It is part of antioxidant defenses.
2. Preformed vitamin A (retinol) is abundant in fish liver oils, liver, dairy products and egg yolk. Vegetarian sources of vitamin A include green leafy vegetables, and yellow fruits and vegetables such as carrots, papaya, tomatoes, sweet potatoes, mango, broccoli and spinach.
3. Vitamin A deficiency (VAD) of sufficient duration or severity can lead to xerophthalmia, childhood blindness, anemia, decrease host resistance to infection, and increased risk of mortality in under-5 children.
4. Prevalence of night blindness and Bitot's spots, and serum retinol of less than 0.70 µmol/L are used as the indicators for VAD in a community.
5. Treat all children with clinical signs of VAD as early as possible with massive doses of vitamin A.
6. Vitamin A deficiency in the community can be prevented by improving the availability and consumption of vitamin A by dietary diversification and to strengthen the general nutritional standing of the population; food fortification; and targeted mega-dose vitamin A supplementation to preschool children and during pregnancy.

## Chapter 22.10

# Vitamin B Complex Deficiency

Vineeta Gupta

Vitamin B complex includes thiamine (B<sub>1</sub>), riboflavin (B<sub>2</sub>), niacin (B<sub>3</sub>), pyridoxine (B<sub>6</sub>), cobalamin (B<sub>12</sub>), biotin and pantothenic acid, all of which are water-soluble vitamins. Two other nutrients choline and inositol are also considered part of the vitamin B complex group. Specific signs and symptoms related to deficiency of these two compounds have not been described.

B-complex vitamins function as coenzymes in several enzymatic reactions. Lack of any one of the vitamins can interrupt many closely related reactions and lead to diverse clinical manifestations. Poor diet can result in deficiency of one or more B vitamins; therefore, it is usual practice to supplement all the B-complex group of vitamins in a deficient person.

### THIAMINE (VITAMIN B<sub>1</sub>)

Thiamine is composed of two rings thiazole and pyrimidine linked together by a methylene ring. Thiamine diphosphate and thiamine pyrophosphate are two phosphate derivatives of thiamine, which function as cofactors for many enzymes involved in carbohydrate metabolism. Synthesis of neurotransmitters, such as acetylcholine and gamma-aminobutyric acid (GABA) also requires thiamine, both of which are important for nerve conduction. Thiamine requirements are increased during periods of increased metabolism, like fever, pregnancy, lactation and hyperthyroidism. Alcohol interferes with the uptake and transport of thiamine, which can lead to deficiency in chronic alcoholics.

### Dietary Sources

Thiamine is widely distributed in both nonvegetarian and vegetarian foods, such as fish, poultry, pork, yeast, legumes and cereals. It is both heat-labile and water-soluble and also sensitive to pasteurization. As the vitamin is present in the outer layers of the grain, repeated washing of rice may cause loss of the vitamin.

### Absorption

Thiamine is absorbed in the jejunum and ileum. The absorption is inhibited by alcohol consumption and folic acid deficiency. It may also be decreased in patients with gastrointestinal disease. At low concentrations, the absorption is carrier mediated but at high concentrations, the process occurs by passive diffusion.

### Recommended Daily Allowance (ICMR, 2011)

0–6 mo: 0.2 mg; 7–12 mo: 0.3 mg; 1–3 years: 0.5 mg; 4–6 years: 0.7 mg; 7–9 years: 0.8 mg; 10–12 years: male 1.1 mg, female 1.0 mg; 13–15 years: male 1.4 mg, female 1.2 mg; 16–17 years: male 1.5 mg, female 1.0 mg.

### Thiamine Deficiency

Thiamine deficiency can affect many organ systems, particularly the nervous system. Deficiency can occur with malnutrition and consumption of a diet which has high content of thiaminase-rich foods (raw fresh-water fish) or foods rich in antithiamine factors, such as tea and coffee. It has also been seen when polished rice is the staple diet as may occur in periods of food shortage and in refugee camps. Several chronic diseases, such as HIV-AIDS, gastrointestinal diseases and alcoholism may also be associated with thiamine deficiency.

Thiamine deficiency can present with nonspecific signs and symptoms in the early stages, which include anorexia, nausea,

fatigue, irritability and apathy. As the condition progresses, it presents with more definite features. The well-known syndromes associated with thiamine deficiency are beriberi and Wernicke-Korsakoff syndrome.

### Beriberi

Beriberi can affect either nervous system (dry beriberi); or cardiovascular system (wet beriberi). Infantile form occurs in breastfed infants of mothers with thiamine deficiency.

*Dry beriberi* Peripheral neuropathy is a characteristic feature of dry beriberi. There is symmetric impairment of sensory and motor functions. Distal limb segments are affected more than the proximal. Signs and symptoms include tingling, burning, tenderness, decreased tendon reflexes and loss of vibration sense. They can also have ptosis of eye lids and psychic disturbances.

*Wet beriberi* This condition is characterized by edema, tachycardia, cardiomegaly and congestive heart failure. The exact cause of edema is not clear but may be due to cardiac or renal dysfunction. Fatty degeneration of the myocardium has also been described. Untreated condition can rapidly progress leading to fatal outcome. The changes are quickly reversed on thiamine supplementation.

*Infantile beriberi* This can present with either cardiac or neurologic forms of the disease. Infants with cardiac form have tachycardia, dyspnea, cyanosis and cardiomegaly. Neurologic form can present with seizures. Untreated disease can result in death if thiamine is not supplemented rapidly.

### Wernicke Encephalopathy

Wernicke encephalopathy is characterized by the triad of ophthalmoplegia, ataxia, and mental changes. Classically thought to be a disease of chronic alcoholics, but may be seen in severely undernourished infants and children also. It has also been reported post bariatric surgery.

*Treatment* Diagnosis can be confirmed by demonstration of decreased levels of RBC transketolase. Oral administration of thiamine may be adequate in the absence of gastrointestinal disturbances. Children with cardiac failure and neurological features require 10 mg thiamine intramuscular or intravenous for 1 week followed by 3–5 mg per day for 6 weeks. Several weeks of treatment is needed for complete cure.

### RIBOFLAVIN (VITAMIN B<sub>2</sub>)

Riboflavin acts as coenzyme in many metabolic pathways and mitochondrial respiratory chain.

### Dietary Sources

Riboflavin is distributed in meats, eggs, milk, legumes, mushrooms and vegetables such as broccoli and spinach. It is resistant to heat and pasteurization but destroyed by light.

### Recommended Daily Allowance

0–6 mo: 0.3 mg; 7–12 mo: 0.4 mg; 1–3 years: 0.6 mg; 4–6 years: 0.8 mg; 7–9 years: 1.0 mg; 10–12 years: male 1.3 mg, female 1.2 mg; 13–15 years: male 1.6 mg, female 1.4 mg; 16–17 years: male 1.8 mg, female 1.2 mg.

### Deficiency

Riboflavin deficiency is observed in malnutrition and malabsorption disorders. Prolonged gastrointestinal infections and diarrhea are other causes. Phenothiazines, probenecid and oral contraceptives can also cause riboflavin deficiency.

## Clinical Features

Riboflavin deficiency presents with cheilosis (**Fig. 1**), glossitis, keratitis, conjunctivitis, photophobia, lacrimation and seborrheic dermatitis. Cheilosis is observed at the angle of the mouth which starts as pallor and progresses to maceration and fissuring. Fissures extend radially from the angle of mouth. Loss of papillae causes a smooth tongue. Impaired erythropoiesis may lead to normochromic, normocytic anemia. Eye manifestations also include circumcorneal vascularization.

**Figure 1** Angular cheilosis in a child with vitamin B complex deficiency

## Treatment

A well-balanced diet which includes milk and milk products provides adequate amounts of riboflavin. Oral administration of 3–10 mg/day of riboflavin corrects the deficiency. It can be given as part of the vitamin B complex mix.

## NIACIN (VITAMIN B<sub>3</sub>)

Niacin (nicotinamide or nicotinic acid) is a constituent of two cofactors, nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate involved in vital oxidation-reduction reactions. These compounds are important coenzymes for glycolysis, pyruvate metabolism, protein and amino acid metabolism, pentose biosynthesis and fatty acid metabolism. Niacin is essential for functioning of skin, intestinal tract, and nervous system. It is rapidly absorbed from stomach and intestine.

## Dietary Sources

Niacin is widely distributed in both vegetarian and nonvegetarian food sources such as meat, fish, poultry, cereals, legumes and green leafy vegetables. It can also be synthesized from tryptophan in eggs and milk. It is heat stable.

## Recommended Daily Allowance

0–6 mo: 710 µg/kg; 7–12 mo: 650 µg/kg; 1–3 years: 8 mg; 4–6 years: 11 mg; 7–9 years: 13 mg; 10–12 years: male 15 mg, female 13 mg; 13–15 years: male 16 mg, female 14 mg; 16–17 years: male 17 mg, female 14 mg. These intakes are expressed in terms of niacin equivalents (1 mg niacin equivalent = 1 mg niacin = 60 mg tryptophan).

## Deficiency

Niacin deficiency initially presents with nonspecific signs and symptoms such as anorexia, weakness, numbness and dizziness. Chronic and severe niacin deficiency results in classic triad of dermatitis, diarrhea and dementia referred to as *pellagra*. Primary deficiency results from inadequate niacin and/or tryptophan in the diet as occurs in those whose staple diet is maize. It can also occur with prolonged parenteral nutrition without appropriate niacin supplementation, anorexia nervosa and chronic alcoholism. Secondary deficiency can also occur when disease conditions (prolonged diarrhea, ulcerative colitis, tuberculosis of the gastrointestinal tract) interfere with niacin absorption. HIV infection induces pellagra like state which is reversible with nicotinamide treatment.

In the initial stages, cutaneous lesions of pellagra resemble sunburn. Skin becomes red and large blisters or blebs may develop which leave a dusky brown-red coloration on healing. In late stages, the skin is dry, scaly and hyperkeratotic with yellowish brown hue. Later on, it becomes darkly pigmented. The lesions are frequently seen on the dorsal surfaces of the hands, face, neck, arms and feet. In the neck it may be seen in a characteristic necklace like distribution (*Casal necklace*). Lesions may be exacerbated by exposure to sun, heat or friction.

Gastrointestinal tract disturbances include nausea, vomiting, abdominal pain and epigastric discomfort. Diarrhea may occur due to diffuse involvement of the gut. Loss of appetite and malabsorption cause malnutrition and severe weight loss.

Mental disturbances may be unnoticed in the initial stages when patient may be only apathetic and slightly depressed. Later on, neuropsychiatric manifestations may be seen as headache, irritability, fatigue, anxiety, confusion, delusions, hallucinations, tremor and disorientation. With progressive deficiency, patients may become comatosed.

## Treatment

Supplementation of 50–300 mg/day of niacin with a balanced diet rapidly corrects the deficiency. Severe cases or those with poor intestinal absorption may require intravenous niacin. Sun exposure should be avoided for skin lesions and emollients can be applied on the affected areas.

## VITAMIN B<sub>6</sub> (PYRIDOXINE)

Vitamin B<sub>6</sub> acts as a cofactor in many enzymatic reactions related to amino acid biosynthesis and carbohydrate and fatty acid metabolism. It comprises of three pyridine derivatives called pyridoxine, pyridoxal and pyridoxamine. Pyridoxal 5-phosphate is the biologically active form which is involved in the metabolism of many neurotransmitters such as dopamine, serotonin, adrenaline, and GABA. Vitamin B<sub>6</sub> is mainly absorbed in the jejunum.

## Dietary Source

Vitamin B<sub>6</sub> is widely distributed in many kinds of food including meats, pulses, cereals, vegetables and fruits. A small proportion of vitamin B<sub>6</sub> is derived from intestinal bacterial flora. The vitamin is heat-labile and may be lost during high temperature processing of cereals.

## Recommended Daily Allowance

0–6 mo: 0.1 mg; 7–12 mo: 0.4 mg; 1–6 years: 0.9 mg; 7–12 years: 1.6 mg; 13–17 years: 2 mg.

## Deficiency

Infants with vitamin B<sub>6</sub> deficiency present with irritability, apathy, seizures, vomiting and failure to thrive. Electroencephalogram

abnormalities have also been reported. Peripheral neuropathy may be seen in adults. Skin lesions can be seen in form of cheilosis, glossitis and seborrheic dermatitis. Other features associated with vitamin B<sub>6</sub> deficiency include lymphopenia, hyperglycemia, infections and microcytic anemia.

Several vitamin B<sub>6</sub> dependency syndromes due to defects in enzyme structure or function have been described which include vitamin B<sub>6</sub>-dependent seizures, vitamin B<sub>6</sub>-responsive anemia, homocystinuria and cystathioninuria. These syndromes respond to large doses of vitamin B<sub>6</sub>. During treatment of tuberculosis with isonicotinic acid hydrazide (INH), peripheral neuropathy may develop which responds to vitamin B<sub>6</sub>.

### Treatment

Child should consume a balanced diet which includes a variety of foods to meet the normal requirements. Seizures due to vitamin B<sub>6</sub> deficiency respond to 100 mg of pyridoxine. Further doses are not required with good dietary intake. 2–10 mg intramuscular or 10–100 mg oral pyridoxine daily is needed for pyridoxine dependent children.

### FOLIC ACID

Folic acid is composed of a pterin ring connected to para-aminobenzoic acid which is conjugated to one or more glutamate residues. Many naturally occurring and structurally related compounds are collectively known as folates. Folic acid (pteroylglutamic acid) is the synthetic form which is used in food fortification. Pteroylpolylglutamate is the naturally occurring folate in foods. Tetrahydrofolate is the biologically active form.

Folate coenzymes participate in many important reactions, including synthesis of deoxyribonucleic acid and purine and amino acid interconversion. It also converts homocysteine to methionine in conjunction with vitamin B<sub>12</sub> and lowers the risk of cardiovascular diseases. It is also involved in the synthesis of neurotransmitters, such as serotonin which plays important role in the regulation of mood and sleep. Folate deficiency also leads to impaired methylation reactions involved in the regulation of gene expression leading to increased neoplastic risk.

### Dietary Sources

Leafy vegetables such as spinach, turnips, lettuce, dried beans and peas; and sunflower seeds are rich sources of folates cereals, nuts and fruits are also good sources.

### Recommended Daily Intake

Infants (0–12 mo): 25 µg; 1–3 years: 80 µg; 4–6 years: 100 µg; 7–9 years: 120 µg; 10–12 years: 140 µg; 13–15 years: 150 µg; 16–17 years: 200 µg.

### Absorption

Folates are present as polyglutamates in natural foods and tissues. In the plasma, they are found as monoglutamates, the form in which they can be transported across cell membranes. Polyglutamates are converted to monoglutamates by the enzymes in the lumen of the small intestine which are absorbed in the proximal jejunum via both active and passive transport.

### Deficiency

Risk of folate deficiency is increased during periods of rapid growth as in infancy. It can also result from poor nutritional intake, malabsorption (celiac disease, inflammatory bowel disease), increased cell turnover (chronic hemolytic anemia), prolonged drug treatment (methotrexate, 6-mercaptopurine, azathioprine, phenytoin, etc.) and some inborn errors of folate metabolism (methylene tetrahydrofolate reductase deficiency).

### Clinical Features

Folate deficiency causes anemia which typically consists of macrocytosis and hypersegmented polymorphonuclear leukocytes. Anemia progresses slowly and symptoms may not be evident till hematocrit falls to very low levels. Folate deficiency leads to accumulation of homocysteine and high levels of homocysteine are associated with atherosclerotic diseases such as coronary artery disease and stroke.

Maternal folate status has been linked to spontaneous abortion, abruptio placentae and neural tube defects). Folic acid supplementation (400 µg) is recommended in the periconceptional period (1 month before and at least 3 months after) for women of child bearing age to decrease the risk. In several countries like USA and Canada, mandatory fortification of cereal grains has proved effective in reducing the incidence of neural tube defects significantly.

### Treatment

Recommended dietary allowance of folate is 100–300 µg/day. In case of deficiency states such as megaloblastic anemia, therapeutic doses of 1–5 mg/day of folate are needed along with vitamin B<sub>12</sub> for 3–4 weeks. Folate deficiency due to anti-folate medication requires elimination of the offending drug.

### VITAMIN B<sub>12</sub> (COBALAMIN)

Vitamin B<sub>12</sub> is composed of four linked pyrrole rings which surround a cobalt moiety. Methylcobalamin and 5-deoxyadenosyl are the active forms in tissues whereas cyanocobalamin is the commercially available form of B<sub>12</sub>. Vitamin B<sub>12</sub> acts as cofactor for the enzyme involved in conversion of methylmalonyl coenzyme A to succinyl coenzyme A which is an important reaction in the lipid and carbohydrate metabolism. Vitamin B<sub>12</sub> in conjunction with folate participates in conversion of homocysteine to methionine, synthesis of purines and pyrimidines, protein biosynthesis and methylation reactions. It also plays an essential role in the folate metabolism to maintain its cellular levels.

### Dietary Sources

Vitamin B<sub>12</sub> is obtained only from animal sources like muscle meat, eggs, clams, oysters and dairy products. Organs such as liver, heart and kidney have high concentrations of the vitamin.

### Recommended Daily Allowance

0.2 µg for infants and 0.2–1.0 µg for older children and adolescents.

### Absorption

Vitamin B<sub>12</sub> requires *intrinsic factor* for its absorption in the ileum. Intrinsic factor is a glycoprotein which is produced in the stomach. Its absence causes pernicious anemia where there is an inability to absorb ingested vitamin B<sub>12</sub>. A very small fraction of the vitamin is absorbed through passive diffusion. Vitamin B<sub>12</sub> is largely stored in the liver and can take years to deplete before deficiency develops.

### Deficiency

Insufficient dietary intake as in strict vegans who do not consume any animal products and impaired absorption either due to deficiency of intrinsic factor or intestinal or liver disease are common causes of vitamin B<sub>12</sub> deficiency in adults. Some drugs such as anticonvulsants, aspirin, oral contraceptives and alcoholism can also interfere with the absorption of vitamin B<sub>12</sub>. Gastrectomy, gastric bypass and medications suppressing stomach acid production are other causes of vitamin deficiency. As the deficiency takes a long time to manifest, young infants usually

do not present with clinical features unless they are exclusively breastfed by deficient mothers.

### Clinical Features

Manifestations of vitamin B<sub>12</sub> deficiency include glossitis and nonspecific gastrointestinal symptoms like nausea, vomiting and anorexia. Dermatologic signs include hyperpigmentation of the skin (**Fig. 2**), especially noticed on the knuckles and abnormal pigmentation of hair due to increased melanin synthesis. Hematologic manifestations include megaloblastic anemia which has been discussed separately. Subacute combined degeneration of the cord is a specific neurologic manifestation which presents with diffuse and progressive demyelination of the peripheral nerves, spinal cord and central nervous system.

### Treatment

Several protocols are available for treatment of vitamin B<sub>12</sub> deficiency, which will be discussed in the chapter on megaloblastic anemia.

**Figure 2** Hyperpigmentation in a child with vitamin B<sub>12</sub> deficiency

## BIOTIN

Biotin acts as a cofactor in carboxylation reactions which are involved in gluconeogenesis, fatty acid metabolism and amino acid catabolism. Biotin is widely distributed in food stuffs and deficiency is uncommon. Infants and children receiving total parenteral nutrition without biotin supplementation may develop deficiency. It may also occur in persons consuming large quantities of raw egg white which contains avidin, a biotin antagonist. Clinical features of deficiency include dermatitis, conjunctivitis, alopecia and central nervous system abnormalities. Oral administration of 2–5 mg biotin daily for 2–3 weeks corrects the deficiency.

### IN A NUTSHELL

- Vitamin B complex includes thiamine (B<sub>1</sub>), riboflavin (B<sub>2</sub>), niacin (B<sub>3</sub>), pyridoxine (B<sub>6</sub>), cobalamin (B<sub>12</sub>), biotin and pantothenic acid, all of which are water soluble.
- B-complex vitamins function as coenzymes in several enzymatic reactions.
- Poor diet can result in deficiency of one or more B complex vitamins, leading to beriberi (B<sub>1</sub> deficiency), pellagra (niacin deficiency); or megaloblastic anemia (B<sub>12</sub> deficiency).
- Malabsorption syndromes and drugs can cause secondary deficiency of vitamin B complex.
- All the B complex vitamins are supplemented together in a deficient person.
- Folate deficiency has been linked to increased incidence of neural tube defect.
- Folate supplementation is recommended in periconceptual period in women of child bearing age.

## Chapter 22.11

# Vitamin C and Scurvy

Tejinder Singh, Shaveta Kundra

Vitamin C or ascorbic acid is a six carbon compound, structurally related to its precursor, D-glucose. It is a white crystalline, odorless, water-soluble substance with very high melting point (192°C) and a strong reducing agent. The crystalline form remains stable in dark and in dried form while in aqueous form it is attacked by high pH and temperature, atmospheric oxygen and other oxidizing agents. Pure ascorbic acid is synthesized from D-sorbitol (30 g of ascorbic acid/100 g of sugar). L-ascorbic acid and dehydroascorbic (formed from reversible conversion of ascorbic acid) acid are the active forms of vitamin C. The absorption of vitamin C occurs from the gastrointestinal tract in a dose-dependent manner. At lower intakes almost complete absorption occurs by active transport mechanism while at higher intake absorption is reduced and occurs mainly by passive diffusion. The unabsorbed ascorbic acid in the bowel lumen can cause osmotic diarrhea. Gastrointestinal disorders causing its destruction or damage can impair the ascorbic acid absorption. Excretion of ascorbic acid occurs rapidly in urine and to some extent in sweat and feces.

## PHYSIOLOGICAL FUNCTIONS

Vitamin C primarily maintains collagen formation. It acts as a coenzyme in various hydroxylation reactions; e.g., proline to hydroxyproline, an important step in collagen synthesis. It is required for tyrosine metabolism in both children and adults. For example, transient hypertyrosinemia of the newborn, which is relatively common among low-birthweight infants and to a lesser extent in term infants fed high-protein diets, can be corrected by administering ascorbic acid. Vitamin C is effective in wound healing. Deficiency of ascorbic acid leads to impaired collagen formation in the healing wounds. Ascorbic acid also is necessary for conversion of folic acid or other conjugates; deficiency may lead to megaloblastic anemia. Consumption of vitamin C along with iron increases its absorption from the gut by approximately 200–600%. When consumed with food vitamin C increases the bioavailability of both heme and non-heme iron. Vitamin C acts as a reducing agent and lowers the toxicity of several elements, e.g., selenium, nickel, lead and cadmium. The reduced forms of these elements are either poorly absorbed or excreted rapidly. Vitamin C also stimulates the production of interferon and thereby affects immune function. Vitamin C acts as an antioxidant, and plays a role in prevention of infections, protection against the effects of stress and detoxifying chemicals; and as a necessary substance in the regulation of cholesterol.

## SOURCES OF VITAMIN C

Marine fish, fresh fruits, especially citrus fruit, and vegetables (cauliflower, broccoli and cabbage) are good sources of vitamin C. Vitamin C is lost in cooking as a result of heat and oxidation. Vitamin C content of common food item is summarized in **Table 1**. Breastmilk contains adequate vitamin C provided the mother is not deficient in vitamin C. The vitamin C content of cord blood plasma is usually two to four times that of maternal plasma. Bovine milk contains very little vitamin C; thus, infants fed bovine milk formulas must receive vitamin C supplements. The requirement increases in children with febrile illness, particularly infectious and diarrheal diseases; severe malnutrition, children

**Table 1** Vitamin C content of common food items

Food group	Food items	Vitamin C content (mg/100 mg)
Green leafy vegetables	Agathi, cabbage, coriander leaves, drumstick leaves,	120–220
Other vegetables	Capsicum	137
	Green chillies	117
	Tomato	24
Fruits	Amla	600
	Guava	212
	Lemon, orange	50

with prolonged illness or hospitalization on parenteral nutrition. Iron deficiency, cold exposure and protein depletion also increase the need for vitamin C.

## RECOMMENDED DAILY ALLOWANCE (RDA)

The RDA for vitamin C is 25 mg/day for infants and 40 mg/day for older children. The requirement increases to 60–80 mg/day during pregnancy and lactation.

## VITAMIN C DEFICIENCY

Clinical manifestations of deficiency usually develop after several months of inadequate intake due to the relatively slow turnover of connective tissues. However, the symptoms can develop much more rapidly in children due to increased demands of growth. Deficiency of vitamin C results in *scurvy*, a condition in which formation of collagen and chondroitin sulfate is impaired. This results in increased tendency to hemorrhage, defective tooth dentin formation and loosening of the teeth. The shafts and epiphysis of the long bones become rarified due to failure of osteoblastic function and disrupted balance of productive and destructive processes in the bone. Number of proliferating cartilage cells is markedly reduced and their mitosis is impaired; resulting in reduced growth. Calcification of cartilaginous matrix remains uninterrupted. As a result the zone of provisional calcification gets thickened but brittle and liable to fissuring and fractures or epiphysal separation and displacement. Hemorrhage can occur under the periosteum due to capillary permeability, and can cause periosteal stripping and pain; the hematoma subsequently becomes calcified (dumbbell-shaped calcification).

## CLINICAL FEATURES

Scurvy can occur at any age. Since prolonged deprivation of vitamin C is required to deplete the tissue stores, deficiency is unusual in infants less than 6 months. Most commonly it occurs in infants between the ages of 6 months and 24 months, who are fed on boiled milk without supplements. Onset is usually abrupt in an infant who has previously appeared well.

The first symptom is pain and tenderness of the limbs, particularly in the legs. The infant screams when picked up or moved or handled during bathing or while changing the diaper. There may be obvious swelling along the shaft of legs in one or more limbs; usually on the thighs. The child is fretful and assumes a froglike position when at rest with the thighs abducted and knees slightly flexed. The swelling may sometime be extensive and involve the whole thigh. The swelling may become hard after some weeks due to deposition of calcium in the subperiosteal hematoma. The displacement of epiphysis or fragmentation of the calcified matrix at the end of the bone may cause severe pain and restriction of limb movement, resulting in pseudoparalysis.

Dental changes are appreciated after eruption of teeth. The mucous membrane becomes bluish purple, swollen and spongy especially over the upper incisors. The gums may become necrotic and the teeth shed. In severe cases, purpuric spots or spontaneous ecchymoses may appear into the skin. Bleeding may occur in brain (subdural hemorrhage), eyes (subconjunctival hemorrhage) or orbits leading to black eye. Rarely internal bleeding like hematemesis, hematuria or melena may occur. Other features include beading at costochondral junction of ribs—scorbutic rosary, depression of the sternum, moderate anemia and often mild fever. Scorbutic rosary should be differentiated from rachitic rosary (described in differential diagnosis). Anemia is normocytic or macrocytic. Fever of scurvy usually subsides with vitamin C therapy.

## DIAGNOSIS

The diagnosis is suggested by characteristic clinical manifestations, radiographic appearance of the long bones and history of poor vitamin C intake. Estimation of plasma vitamin C concentration or leukocyte vitamin C concentration can aid in diagnosis. Normal plasma vitamin C levels in persons with adequate consumption are 0.4–1.4 mg/dL. A continuously low plasma vitamin C level (< 0.1 mg/dL) can lead to scurvy. Leukocyte vitamin C concentrations are more useful, as these reflect the tissue levels and are independent of plasma concentration. In addition, ascorbic acid concentration of the white cell or platelet layer of centrifuged oxalated blood can be measured. Tissue saturation of vitamin C can be estimated from urinary excretion of the vitamin after test dose of ascorbic acid. In normal children, 80% of the test dose appears in the urine within 3–5 hours after parenteral administration of the test dose (11 mg/kg of ascorbic acid). There can be generalized nonspecific aminoaciduria with normal plasma amino acid concentration. In deficiency state administration of vitamin C results in tissue storage. Once tissue stores are replete, additional administration results in loss in urine. The amount of vitamin utilized can be estimated from the difference between intake and excretion of the vitamin.

## Radiological Signs of Scurvy

The characteristic changes are seen in rapidly growing bones; at shaft and growth cartilage junction (**Fig. 1**). Common sites of involvement are upper end of humerus, knee joint (lower end of femur and upper end of tibia), and sternal ends of the ribs. These signs are characteristic and depend partly on failure of osteoblastic function and partly on the occurrence of hemorrhages. The changes in the acute phase are as follows:

- Generalized osteoporosis of bone involving both the shaft and epiphysis resulting in *ground glass appearance*. There is thinning of cortex of the shaft. It may become mere pencil streak (*pencil point cortex*) or even vanish next to the epiphysal line.
- The epiphysis seems outlined with the rim of increased density standing out against the rarified bone, so called *penciling*—resembling the *signet rings*. A circular, opaque radiologic shadow surrounding the epiphysal centers of ossification is seen, known as *Wimberger sign*.
- Thickening and widening of zone of provisional calcification occurs, known as *white line of Frankel*.
- A transverse band of radiolucency appears secondary to poorly formed trabeculae in the metaphysis subjacent to the zone of provisional calcification, known as *Trümmerfeld zone* or *scurvy line*.
- The lateral projection of the calcified matrix beyond the usual limits of the shaft forms a spur (*Pelkan spur*). This is also known as *corner sign* and provides one of the most diagnostic features of scurvy. Pelkan spurs are associated with fractures of the Trümmerfeld zone and periosteal elevation.

**Figure 1** Radiological changes in scurvy  
Source: Dr Elizabeth KE, Thiruvananthapuram, Kerala.

- Adjacent to the dense calcified line, atrophy of the sub-epiphysal cortex and spongiosa casts a narrow zone of rarefaction involving the lateral aspects of the white line, which may result in partial separation of the epiphysal plate.
- Fissuring and fractures of the calcified metaphysis are common because in spite of denseness of the shadow, *the plate is brittle*. On the other hand, in spite of the cortical atrophy, diaphysal cortical fractures are rare.
- Displacement of the epiphysis, when it occurs, is indicated by faulty alignment of the epiphysal line in the shaft. Partial separation without displacement, which is more common, shows as a crack extending only part way across.
- Large subperiosteal hematomas produce regional increases in the soft tissue density. Later, calcification occurs in the hematoma, which shows in X-rays as a shell enveloping the shaft.
- In extreme cases, the X-ray skull may show *hair-on-end appearance* due to porotic hyperostosis or secondary to marrow hyperplasia in response to anemia. No changes occur in the sphenoid.

During healing, the cortex becomes thicker, spongiosa more clearly defined and the rarefied transverse areas at the ends regain normal density. Where there has been lateral displacement of the epiphysal cartilage, the new shell of the bone on the cortex aligns itself with the displaced epiphyses on treatment, leaving no permanent deformity. The contour of the shaft will be altered by the surrounding calcification for long after, but ultimately normal contour is re-established without any permanent deformity.

## DIFFERENTIAL DIAGNOSIS

The diagnosis is usually clinical with characteristic clinical features like pain and tenderness in the limbs with or without joint swelling, spongy gums and scorbutic beading of ribs. However, swelling of limb has to be differentiated from traumatic swellings (redness and warmth), osteomyelitis (high fever and leukocytosis) and osteochondritis of congenital syphilis (seen in infants < 6 months).

Pseudoparalysis of scurvy should be differentiated from that in congenital syphilis (occurs in smaller infants) from fracture (palpable fracture or crepitus) and from paralysis of poliomyelitis. In pseudoparalysis, painful stimulation of extremity will indicate that actual paralysis is not there.

In scorbutic beading, there is an abrupt step down from the rib to its cartilage, best appreciated by running a finger run along from

the lateral aspect of the rib towards the sternum. It occurs probably due to backward dislocation of the sternum due to hemorrhage between the end of the rib and the cartilage. In contrast, rickety rosary appears as rounded knobs, formed by enlargement of costochondral junction. Beading in rickets feels as a gradual sloping off to the cartilage.

The classical radiological signs like ground glass appearance, penciling of bones, dense white line at epiphysial ends with adjacent translucency and spurs usually confirm the diagnosis. However, osteoporosis alone is nonspecific. In septic arthritis radiological changes occur in the involved limb. In contrast, X-ray changes in the bones in scurvy are widespread and symmetrical. Even if scorbutic disability is confined to the upper limbs, characteristic changes can be seen in X-ray of lower extremities.

In infantile cortical hyperostosis, X-ray appearance resembles healing scorbutic lesion but absence of other features distinguishes between the two. Radiological features of epiphyseal separation or periosteal reaction can be seen in battered baby or child abuse; changes are generalized associated with multiple fractures.

## MANAGEMENT

Response to vitamin administration is dramatic. The daily therapeutic dose is 100–200 mg, oral or parenteral. Oral route permits slower absorption and is preferable to parenteral route. Intramuscular injections are avoided. Also, large amount of vitamin C is lost in urine if given by IV route. Intake of vitamin C is improved by consumption of fresh citrus fruits, orange or tomato juice. Recovery, including resumption of normal growth, is rapid with proper treatment. However, for complete recovery, prolonged treatment for up to 3 months should be taken. Pain and tenderness disappear within a week. Persistence of tenderness suggests separation of an epiphysis. Radiological improvement can be noted after 1–2 weeks of therapy with 500 mg vitamin C given orally. Even after marked displacement of an epiphysis, the alignment between the shaft and the epiphysial fragment is gradually restored with

laying down of new bone. Local treatment of the extremities is not required. The swelling of subperiosteal hemorrhage may take months to disappear.

## PREVENTION

Scurvy can be prevented by an adequate intake of vitamin C. Exclusive breastfeeding provides protection against vitamin C deficiency throughout infancy. Nonbreastfed babies should receive either vitamin C fortified formulas or adequate vitamin C-rich foods in infancy if consuming heat-treated milk. Increased supplementation is required in malnourished children and during pregnancy and lactation.

### IN A NUTSHELL

- Vitamin C is a water-soluble vitamin, lost in cooking as a result of heat and oxidation.
- Fresh citrus fruit and vegetables (cauliflower, broccoli and cabbage) are good sources of vitamin C.
- Deficiency results in scurvy; manifests as petechial hemorrhages, painful and swollen bones, and poor wound healing.
- Diagnosis is clinically supported by radiological changes.
- Oral supplementation produces dramatic improvement in symptoms.

## Chapter 22.12

## Vitamin D, Nutritional Rickets and Hypervitaminosis D

*S Balasubramanian*

Vitamin D refers to the precursors of the active secosteroid hormone 1,25-dihydroxyvitamin D<sub>3</sub> (1,25-OH<sub>2</sub> D<sub>3</sub>), named as calcitriol. Recognition of rickets as a childhood bone disease led to the discovery of vitamin D, a fat-soluble prohormone. In the beginning of 20th century, the antirachitic effect of cod liver oil was first described. Evidence for the fact that there are benefits extending beyond bones has resulted in renewed interest in this direction. An increasing variety of noncalcemic actions is reported in the recent times, particularly those related to decreasing risk of common cancers, autoimmune diseases, infectious diseases, heart disease, neurocognitive disorders, psychiatric illnesses, allergy, asthma, diabetes mellitus, pain and even mortality.

## EPIDEMIOLOGY OF VITAMIN D DEFICIENCY

Vitamin D deficiency is considered as the most under-diagnosed and under-treated nutritional deficiency in the world and is widely prevalent in all parts of the world irrespective of age, gender, race and geography. The prevalence in India is reported to be as high as 70–100% in the general population. The reasons for this are factors, such as non-fortification of dairy products, socioreligious and cultural practices not facilitating adequate sun exposure. As a consequence, subclinical vitamin D deficiency is prevalent in epidemic proportions in both urban and rural settings, and across all socioeconomic and geographic strata in the society. The other reasons for the high prevalence include vegetarianism, low calcium intake, high phytate diet, lactose intolerance and genetic factors.

## ETIOLOGY OF VITAMIN D DEFICIENCY

Vitamin D deficiency is common in infants who are dark-skinned and exclusively breastfed beyond 3–6 months of age, particularly in the background of maternal vitamin D deficiency during pregnancy or prematurity. Vitamin D deficiency is also common among children who are on vegetarian and unusual diets, use anticonvulsant or antiretroviral medications, or those with malabsorption. Additional risk factors include residence at higher latitudes, winter season, and other causes of low sun exposure (**Box 1**). Genetic pleomorphism predisposing individuals to vitamin D deficiency rickets has been recently reported.

## VITAMIN D METABOLISM

Vitamin D<sub>2</sub> (ergocalciferol) is obtained only from diet, whereas vitamin D<sub>3</sub> (cholecalciferol) is found in cod liver oil and oily fish and is the form synthesized in skin. Sunlight, specifically ultraviolet B rays in the 290–315 nm range, converts 7-dehydrocholesterol (present in skin) to previtamin D<sub>3</sub>. At normal skin temperature, previtamin D<sub>3</sub> thermally isomerizes during a period of hours to vitamin D<sub>3</sub>. It binds to vitamin D-binding protein and is transported to the liver for 25-hydroxylation and then to the kidney. The vitamin D binding protein-25OHD complex is excreted and then reabsorbed in the proximal tubule through the endocytic receptors megalin and cubilin, where it undergoes 1-hydroxylation by CYP27B1 resulting in the active metabolite 1,25-dihydroxyvitamin D [calcitriol, 1,25(OH)<sub>2</sub>D]. 1,25(OH)<sub>2</sub>D binds to the vitamin D receptor, which heterodimerizes with the retinoic acid receptor, to form a ligand-receptor complex that targets specific response elements on the genome (**Fig. 1**).

## BOX 1 Etiology of vitamin D deficiency

## Disorders of vitamin D synthesis

- Increased skin pigmentation
- Topical application of sunscreen agents
- Overclothing preventing sunlight exposure
- High-rise buildings and urbanization

## Geographical location

- Latitude (> 400 north or south)
- Winter season
- Air pollution, cloud cover
- High altitude
- Avoidance of sunlight for cosmetic reasons and fear of skin cancer

## Decreased intake of vitamin D—vegetarianism

## Decreased maternal vitamin D stores and exclusive breastfeeding

## Malabsorption

- Celiac disease
- Pancreatic insufficiency
- Chronic cholestasis

## Decreased synthesis or increased degradation of 25(OH)D

- Chronic liver disease
- Drugs (rifampicin, isoniazid, antifungals, anticonvulsants)
- Genetic factors.

Figure 1 Vitamin D metabolism

## MECHANISM OF ACTION

Maintaining an adequate level of serum calcium and phosphorus is the most important biochemical function of vitamin D without which only 10–15% of dietary calcium and about 60% of phosphorus will be absorbed. Vitamin D receptors exist in a variety of cells responsible for the biological effect on more than mineral metabolism. The primary action of 1,25(OH)<sub>2</sub>D is to stimulate intestinal calcium absorption. Vitamin D sufficiency increases calcium and phosphorus absorption. The interaction of 1,25(OH)<sub>2</sub>D with its receptor in the osteoblast stimulates the expression of receptor activator of a nuclear factor ligand, which interacts with receptor activator of a nuclear factor resulting in induction of immature monocytes to become mature osteoclasts, which in turn results in dissolution of the matrix and mobilization of calcium and other minerals from the skeleton. In addition, 1,25(OH)<sub>2</sub>D also stimulates calcium reabsorption from the glomerular filtrate.

Most tissues and cells in the body contain receptors for 1,25(OH)<sub>2</sub>D which has a wide range of biological actions, including inhibiting cellular proliferation and inducing terminal differentiation, inhibiting angiogenesis, stimulating insulin production, inhibiting renin production, and stimulating macrophage cathelicidin production. In addition, 1,25(OH)<sub>2</sub>D stimulates its own destruction

by enhancing the expression of the 25-hydroxyvitamin D-24-OHase (CYP24R) to metabolize 25(OH)D and 1,25(OH)<sub>2</sub>D into water-soluble inactive forms. Several tissues and cells possess 1-OHase activity. Locally produced 1,25(OH)<sub>2</sub>D in various tissues may be involved in the regulation of up to 200 genes, thereby facilitating many of the pleiotropic health benefits due to vitamin D. Though the conversion to the active 1,25(OH)<sub>2</sub> form is tightly regulated by parathyroid hormone (PTH) and low levels of calcium and phosphorus, the conversion of D to 25(OH)D is not well regulated. PTH is released from the parathyroid gland in response to decreased calcium and/or elevated phosphorus levels. PTH stimulates the kidneys to increase calcium resorption and activate CYP27B1 to synthesize more 1,25(OH)<sub>2</sub>D and activates osteoblasts that facilitate the conversion of preosteoclasts to osteoclasts. Osteoclasts dissolve bone to free up calcium to correct the effects of deficiency that originally activated the parathyroid gland to secrete PTH. Production of excess of active vitamin D is inhibited by a negative feedback loop. 1,25(OH)<sub>2</sub>D inhibits PTH, stimulates the release of fibroblast growth factor 23 (FGF23) from osteoblasts, and also induces the enzyme CYP24A1. FGF23 reduces circulating phosphorus by altering kidney production of a sodium-phosphorus cotransporter and inhibits the vitamin-D-activating enzyme CYP27B1. CYP24A1 enzyme places a hydroxyl group on C-24 of 1,25(OH)<sub>2</sub>D, facilitating its metabolism into calcitriol and subsequent excretion in the bile.

## DAILY REQUIREMENTS AND SOURCES

For most humans, vitamin D comes from exposure of the skin to sunlight. When compared with ingested vitamin D, what is produced in the skin may last at least twice as long in the blood. The recommended dietary allowance of vitamin D for children 1–18 years, pregnant and lactating women is 600 IU (15 mcg) daily. This intake can be provided in the diet or as a vitamin D supplement. The estimated adequate intake for infants up to 12 months is 400 IU (10 mcg) daily. Routine supplementation of vitamin D to exclusively breastfed infants is yet not recommended in India.

The present recommendations for dietary vitamin D intake are primarily based upon the beneficial effects of calcium and vitamin D on skeletal health. The evidence supporting a benefit of vitamin D on extraskeletal outcomes has so far been weak, inconsistent, inconclusive as to causality and insufficient and, therefore, has not been used as a basis for dietary reference intake development.

## RICKETS

The pathological definition of rickets, the failure to mineralize newly formed bone, means that preformed osteoid is unmineralized (osteomalacia) and endochondral calcification at the growth plate is absent or reduced with associated growth-plate deformity. Rickets and osteomalacia are both disorders of deficient mineralization of organic matrix, but with fundamental differences. Rickets is a disease of the physes (growth plates) characterized not only by deficient mineralization of cartilage and osteoid but also by retarded endochondral ossification, which causes excessive accumulation of physal cartilage, growth failure and skeletal deformities. The abnormalities of mineralization and ossification are caused by insufficient circulating levels of calcium and phosphate ions. As rickets is a disorder of open growth plates, it is seen only in children and manifests mostly during infancy (usually less than 18 months of age) and the adolescent growth spurt. In osteomalacia, an insufficient  $\text{Ca} \times \text{P}$  product causes failure of normal mineralization of osteoid, laid down either at sites of bone turnover or by the periosteum in the process of membranous bone formation. These processes occur in both adults and children. Hence, osteomalacia can be present at any age. Abnormalities of mineral ion homeostasis lead to skeletal deformity by disrupting endochondral ossification rather than just causing deficient mineralization of cartilage and osteoid.

## Staging of Rickets

### Stage I

Following vitamin D deficiency, intestinal absorption of calcium declines causing hypocalcemia, which can be clinically silent or lead to seizures or other manifestations. In response, secondary hyperparathyroidism (HPTH) develops, mobilizing calcium and phosphate from bone, increasing renal calcium reabsorption and phosphate excretion, and upregulating renal 25-hydroxyvitamin D-1 $\alpha$ -hydroxylase (1-OHase) to increase calcitriol and, hence, intestinal calcium absorption.

### Stage II

There is normalization of circulating calcium. PTH and alkaline phosphatase (ALP) are elevated and there is hypophosphatemia. Calcitriol levels can be elevated at this time, hence, their measurement is generally not useful in the diagnosis of vitamin D deficiency. At this stage, physal manifestations of rickets become apparent clinically and radiographically.

### Stage III

With worsening vitamin D deficiency, substrate 25-hydroxyvitamin D (25D) levels fall low enough that calcitriol can no longer be maintained despite PTH stimulation of 1-OHase. This leads to decreased intestinal calcium absorption, return of hypocalcemia, worsening of secondary HPTH, and florid clinical and radiographic features of rickets.

## Clinical Features

Florid skeletal features are most prevalent between 3 months and 18 months of age due to development of deformities of weight-bearing limbs. In infants, deformities occur in the forearms, whereas, in toddlers, bow legs (genu varum) (**Fig. 2**) or knock knees (genu valgum) are often seen. Craniotabes, poor growth in height and weight, frontal bossing of the skull, swelling of wrists, knees and ankles and increased sweating are frequently present. *Rachitic rosary* (**Fig. 3**) due to expansion of the costochondral junctions and an inward diaphragmatic pull of the soft rib cage gives rise to Harrison's sulcus (groove). Dentition may be delayed, and development of tooth enamel may be impaired. Irritability, secondary to bone pain, is a common feature in rachitic infants. Muscle weakness leads to hypotonia and delayed motor development, such as late walking. Adolescents with rickets usually present with vague symptoms, such as aches and pains in lower limbs, often with exercise. Muscle weakness and the proximal myopathy may cause difficulty in climbing stairs. Hypocalcemic tetany may occur in adolescents. Florid signs of rickets are rare in adolescents. Pelvic deformities that develop during female adolescence can later lead to obstructed labor due to cephalopelvic disproportion.

## Diagnosis

### Biochemical Changes

Elevated ALP is a reliable marker of disease activity because it participates in the mineralization of bone and growth plate cartilage. ALP levels are normal up to 500 IU/L in neonates and 1,000 IU/L in children up to 9 years of age and decrease after puberty. Serum phosphorus concentrations usually are low in both calcipenic and phosphopenic rickets. Serum calcium levels are usually low in calcipenic rickets, but may be normal in some stages of the disease due to secondary HPTH. The serum concentration of PTH is elevated in calcipenic rickets but is normal in phosphopenic rickets (**Table 1**).

### Radiographic Findings

The following findings may be seen: (a) widening of the epiphyseal plate; (b) cupping and splaying of the epiphyseal end

of metaphysis with stippling and formation of cortical spurs; (c) delay in appearance of the epiphyseal bone centers which are small and osteopenic; (d) osteopenic shafts of the long bones and thin cortices; (e) fuzzy trabecular pattern which is coarse, with a ground-glass appearance; and (f) deformed shafts of the long bones (**Figs 4 and 5**). Extreme deficiency *may lead to* pathological fractures and looser zones (Milkman's fractures). Looser zones are pseudofractures, narrow radiolucent lines, 2–5 mm wide, with sclerotic borders, and are typical findings in osteomalacia and are bilateral and symmetric and lie perpendicular to the cortical margins of bones. *Milkman syndrome* is the combination of multiple, bilateral and symmetric pseudofractures.

### Bone Mineral Density

In those with osteomalacia related to vitamin D deficiency, markedly reduced spine, hip and forearm bone density [as measured by dual-energy X-ray absorptiometry (DXA)] may be observed though bone mineral density (BMD) is not necessarily required for the diagnosis of osteomalacia, and reduced BMD does not distinguish osteoporosis from osteomalacia.

### Vitamin D Levels

Measurement of 25(OH)D levels is the ideal tool to assess vitamin D status. 25(OH)D is the main circulating form of vitamin D and has a half-life of 2–3 weeks in contrast to 1,25(OH)<sub>2</sub>D which has a shorter

**Figure 2** Bowlegs and double malleoli in a child with rickets

**Figure 3** Rachitic rosary

**Figure 4** Skiagram of the chest showing widening of the anterior ends of the ribs and decreased bone density

**Figure 5** Skiagram of the wrist showing cupping, fraying and decreased bone mineral density

**Table 1** Stages of vitamin D deficiency in relation to biochemical markers and radiographic features

Stages	Plasma calcium	Plasma phosphorus	ALP	PTH	25(OH)D	1,25(OH) <sub>2</sub> D3	Radiography
Early	N / ↓	↓	↑	↑	↓	N	Osteopenia
Moderate	N / ↓	↓	↑	↑↑	↓	↑	Rachitic changes 1+
Severe	↓↓	↑↓	↑↑	↑↑	↓↓	↑ / N / ↑	Rachitic changes 2+

half-life of about 4 hours. Measurement of  $1,25(\text{OH})_2\text{D}$  is neither reliable nor recommended for assessment of vitamin D stores. For children with calcipenic rickets, measurement of serum  $25(\text{OH})\text{D}$  helps to distinguish rickets caused by vitamin D deficiency from other causes of calcipenic rickets. Serum concentration of  $25(\text{OH})\text{D}$  accurately reflects the amount of vitamin D stored in the body, and, hence is low in nutritional rickets, whereas it is normal or slightly increased in the other forms of rickets.  $1,25(\text{OH})_2\text{D}$  can be low, normal or increased in calcipenic rickets.  $1,25(\text{OH})_2\text{D}$  levels paradoxically may initially increase in response to rising levels of PTH, but may subsequently decrease because its substrate,  $25(\text{OH})\text{D}$ , is limited but is always increased in VDDR type II and hypophosphatemic rickets.

Majority of children with vitamin D deficiency rickets have serum  $25(\text{OH})\text{D}$  concentrations less than 25 nmol/L (10 ng/mL), and often less than 12.5 nmol/L (5 ng/mL), though serum  $25(\text{OH})\text{D}$  concentrations may not be markedly reduced in overtly rachitic children who have low dietary calcium intake. The most widely accepted standards for defining vitamin D status in children and adolescents are: vitamin D *sufficiency*:  $25(\text{OH})\text{D}$  more than or equal to 20 ng/mL; vitamin D *insufficiency*: 15–20 ng/mL; and vitamin D *deficiency*:  $\leq 15$  ng/mL. A level less than 5 ng/mL has been considered as an indicator of *severe deficiency* (Table 2). Values of more than 100 ng/mL are considered as vitamin D *excess* and above 150 ng/mL as *intoxication*.

## Treatment

The ideal treatment for vitamin D deficiency consists of administration of vitamin  $\text{D}_3$  (cholecalciferol) since ergocalciferol ( $\text{D}_2$ ) is not widely available. The dose recommended for treatment of vitamin D deficient rickets is 1,000 IU daily for newborns less than 1 month, 1,000–5,000 IU daily for infants 1–12 months old, and 5,000–10,000 IU daily for children 1 year and older. Treatment should be continued until there is biochemical evidence of recovery and radiographic evidence of healing which usually occurs by 12 weeks. Thereafter, the dose of vitamin D can be reduced to 400 IU/600 IU daily. Calcium intake should be maintained at 50–75 mg/kg of elemental calcium per day in three divided doses to avoid *hungry bone syndrome*. Skeletal deformities regress completely if appropriate medical therapy is given.

*Stoss therapy* consists of administration of (a) high dose of oral vitamin D (600,000 IU) given on a single day, then maintained at 400–1,000 IU of vitamin D per day; or (b) 50,000 IU of vitamin  $\text{D}_2$  weekly for 8 weeks orally (teenagers) followed by 400 IU/day. This regime however, has a potential for hypercalcemia. Lesser doses of 150,000 or 300,000 IU have been reported to be equally effective with lesser side effects. Since normalization of vitamin D status may not be achieved after 12 weeks even in those given single high

**Table 2** Vitamin D status based on  $25(\text{OH})\text{D}$  levels

Vitamin D status	Levels
<i>US IOM classification</i>	
Severe deficiency	$\leq 12.5$ nmol/L or 5 ng/mL
Deficiency	$\leq 37.5$ nmol/L or 15 ng/mL
Insufficiency	37.5–50 nmol/L or 15–20 ng/mL
Sufficiency	50–200 nmol/L or 20–100 ng/mL
Excess	$> 250$ nmol/L or $> 100$ ng/mL
Intoxication	$> 375$ nmol/L or $> 150$ ng/mL
<i>US Endocrine Society classification</i>	
Deficiency	$< 20$ ng/mL (50 nmol/L)
Insufficiency	21–29 ng/mL (52.5–72.5) nmol/L
Sufficiency	$> 30$ ng/mL
Toxicity	$> 150$ ng/mL

1 mcg = 40 IU; 0.025 mcg is 1 IU

dose stoss therapy, it is necessary to recheck the vitamin D status 12 weeks after initiating therapy (Table 3).

## Prevention

Sun exposure allows for cutaneous vitamin D synthesis. During most seasons, 10–15 min of sun exposure near midday is sufficient for adequate vitamin D synthesis in light-skinned individuals. However, darker skin pigmentation, winter season, or northern latitudes can markedly reduce skin synthesis of vitamin D and increase the need for dietary sources. Studies are necessary to assess the impact of these recommendations in dark-skinned children, and it is possible that relaxation of these measures in dark-skinned children will allow for sufficient cutaneous vitamin D synthesis in the summer months, particularly at lower latitudes.

*American Academy of Pediatrics* recommends that all exclusively breastfed infants should receive 400 IU/day of vitamin D supplements, based on the fact that breastmilk has very low vitamin D content, and that cutaneous vitamin D synthesis from sun exposure is inconsistent and unpredictable. At present, there are no such recommendations for Indian infants. Standards for defining vitamin D sufficiency in healthy children are not well established. In children, radiological changes of rickets and low bone density have been reported at  $25(\text{OH})\text{D}$  levels of less than 16–18 ng/mL (40–45 nmol/L), and ALP levels have been noted to rise at  $25(\text{OH})\text{D}$  levels less than 20 ng/mL (50 nmol/L). At this time, there is little evidence from studies in children to indicate that vitamin D levels above the threshold of 20 ng/mL (50 nmol/L) are necessary to optimize calcium absorption or bone density.

**Table 3** Treatment regimens for vitamin D deficiency

Age group	Daily regimen (8–12 weeks)	Weekly regimen (8–12 weeks)	Stoss therapy	Maintenance dosage
$< 1$ month	1,000 IU	50,000 IU*	Not Recommended	400–1,000 IU/day
1–12 month	1,000–5,000 IU	50,000 IU	1 lakh–6 lakhs units over 1–5 days oral (preferably 3 lakhs)**	400–1,000 IU/day
1–18 years	5,000 IU	50,000 IU	3–6 lakhs units over 1–5 days oral**	600–1,000 IU/day
Any age with obesity, malabsorption syndrome or those on medications affecting vitamin D status	6,000–10,000 IU/day			3,000–6,000 IU/day

\* To convert (IU) to mcg of calciferol, divide by 40.

\*\* Parenteral (intramuscular) therapy—best avoided unless there is severe malabsorption or concern for compliance to oral regimens.

## VITAMIN D TOXICITY

Despite robust skin production, vitamin D toxicity cannot occur from skin production. This is due to the fact that once maximum cutaneous production occurs, additional sun exposure will not result in additional net input to the system. The same ultraviolet B (UVB) that produces vitamin D in the skin also degrades it, causing a steady state that limits cutaneous production to a maximum of ~20,000 IU/day. There have been no reports of vitamin D toxicity from either sun exposure or from exposure to artificial UVB light. The intake at which the dose of vitamin D becomes toxic is not clear. The suggested *tolerable upper intake level* (UL) for vitamin D is 100 micrograms (4,000 IU) daily for healthy adults and children 9–18 years.

Vitamin D intoxication generally occurs after inappropriate use of vitamin D preparations. Symptoms of acute intoxication are due to hypercalcemia and include confusion, polyuria, polydipsia, anorexia, vomiting, and muscle weakness. Long-term intoxication can cause bone demineralization and pain. In children, the hypercalcemia can cause brain injury. Chronic intoxication may cause nephrocalcinosis and bone demineralization (**Box 2**). Diagnosis of vitamin D toxicity is confirmed by high serum calcium, high serum vitamin D 25(OH) and normal PTH.

### Treatment

The main goal of treatment is correction of hypercalcemia. Emergency intervention is necessary when the calcium exceeds 14 mg/dL. Effects of toxicity may last for months because of storage in fatty tissues. Treatment measures include: discontinuation of intake; diet low in calcium and phosphorus. Acute toxicity will require intravenous hydration with saline; and loop diuretics, furosemide. Corticosteroids, calcitonin and bisphosphonates have also been used.

#### BOX 2 Symptoms of vitamin D toxicity

Hypercalcemia  
Hypercalciuria  
Kidney stones  
Hyperphosphatemia  
Polyuria  
Polydipsia  
Ectopic calcification of soft tissues (kidney and lung)  
Nausea/vomiting  
Anorexia  
Constipation  
Headache  
Hypertension

## IN A NUTSHELL

1. There has been increasing interest in the recent times on the role of vitamin D, the sunshine hormone not only in skeletal disorders but also in relation to its benefits on extraskeletal health.
2. There is a high prevalence of vitamin D deficiency in India cutting across age, sex and geographical location.
3. The options available for prevention of vitamin D deficiency include sensible sunlight exposure, changes in dietary habits, routine supplementation and food fortification.
4. Nutritional rickets manifests mostly in infants and toddlers with bony deformities. Vitamin D deficiency in infancy may also present with hypocalcemic seizures.
5. Measurement of 25(OH)D levels is the ideal method to determine and define the vitamin D status. Measurement of alkaline phosphatase levels in plasma is a useful screening test for vitamin D deficiency.
6. Treatment of deficiency with vitamin D<sub>3</sub> with a variety of regimens have been recommended which are equally effective.
7. Hypervitaminosis D manifesting with features of hypercalcemia needs to be recognized early and appropriately treated to prevent serious consequences.

## Chapter 22.13

# Iodine Deficiency Disorders

Umesh Kapil, Neha Sareen

Iodine deficiency is the most prevalent and most common preventable cause of mental deficiency in the world today. Iodine-deficiency disorders (IDDs), which may originate before birth, jeopardize children's mental health and often their very survival. Serious iodine deficiency during pregnancy can result in stillbirth, spontaneous abortion and congenital abnormalities, such as cretinism, a grave, irreversible form of mental retardation that affects people living in iodine-deficient areas. IDDs refer to all of the consequences of iodine deficiency in a population that can be prevented by ensuring an adequate intake of iodine.

Iodine is one of the essential elements required for normal human growth and development. Its daily per capita requirement is 150 micrograms. Iodine is also required for the synthesis of the thyroid hormones, thyroxine (T<sub>4</sub>) and triiodothyronine (T<sub>3</sub>). These hormones which are iodinated molecules of the essential amino acid tyrosine regulate cellular oxidation and, hence, affect calorogenesis, thermoregulation and intermediary metabolism. The thyroid hormones are necessary for protein synthesis, and they promote nitrogen retention, glycogenolysis, intestinal absorption of glucose and galactose, lipolysis and uptake of glucose by adipocytes. Synthesis and secretion of T<sub>4</sub> and T<sub>3</sub> are under the control of the thyroid-stimulating hormone (TSH) which is secreted from the anterior lobe of the pituitary gland. TSH stimulates iodide transport from the blood into thyroid cells, oxidation of iodide to iodine, and iodine binding to tyrosine. Synthesis of thyroid hormones is regulated by the levels of circulating free T<sub>4</sub> and T<sub>3</sub> as a negative feedback mechanism.

## RECOMMENDED DAILY INTAKE

- 90 µg for preschool children (0–59 months);
- 120 µg for schoolchildren (6–12 years);
- 150 µg for adolescents (above 12 years) and adults;
- 250 µg for pregnant and lactating women.

Eating seafood does not ensure adequate dietary iodine sufficiency. Iodine deficiency in population residing at sea coast has been documented from pockets of Azores, Bangkok, Manila, Goa, Mumbai, Kerala, Andaman and Nicobar Islands. New areas, which were relatively free of this problem, are now being identified as iodine-deficient possibly because of intensive agricultural technologies and multiple cropping.

Presence of certain substances (goitrogens) which adversely influence the utilization of iodine in staple foods is also recognized as one of the etiological factors for IDD. They are generally present as thioglycosides or glucosinolates, the glucan portion of which is responsible for its goitrogenicity. Other chemical substances, such as thiocyanates, thio-oxazolidinone, flavonoids, disulfides, phenols, phthalates, biphenyls and lithium, found in environment are also included in goitrogens category. These goitrogens are known to interfere with iodine metabolism at various stages or levels. Some of these substances are found in abundance in certain tubers and vegetables, like tapioca, cabbage and cauliflower.

## PATHOPHYSIOLOGY

Iodine is present in the soil and is ingested through foods grown on that soil. Iodine is present in the superficial layers of the soil and absorbed by crops grown on it. Glaciations, heavy snow and heavy rain leach away iodine from the soil. The erosion of soils in

riverine areas due to loss of vegetation for agricultural production, overgrazing by livestock, and tree-cutting for firewood results in a continued and increasing loss of iodine from the soil. Groundwater and food grown locally in these areas lack iodine. Consumption of crops and plants grown on iodine deficient soils leads to iodine deficiency in populations solely dependent on this vegetation for their iodine requirements. Iodine deficiency in food and water leads to less availability of iodine to thyroid gland for synthesis of T<sub>3</sub> and T<sub>4</sub>. As a result, the thyroid gland becomes hyperactive to produce the requisite amounts of T<sub>3</sub> and T<sub>4</sub> thereby enlarging itself by hyperplasia. This enlargement of the thyroid gland is known as goiter.

The healthy human body contains 15–20 mg of iodine, of which about 70–80% is present in the thyroid gland. The thyroid gland which weighs only 15–20 g possesses a remarkable concentrating power for iodine. Thyroid function is essential for normal growth and development. Thyroid hormone deficiency, whether produced by removal or absence of the thyroid due to disease or congenital defects is associated with severe retardation of growth and maturation of almost all organ systems. The most critical period for the brain in human life cycle is from the second trimester of pregnancy to the first year after birth. In areas of iodine deficiency, where thyroid hormone levels are low, brain development is impaired. In its most extreme form, this result in cretinism, but of much greater public health importance are the more subtle degrees of brain damage and reduced cognitive capacity which affects the entire population. As a result, the mental ability of normal children living in areas of iodine deficiency is reduced.

Simple goiter is due to a lack of iodine in diet due to iodine deficiency in soil, ingestion of a goitrogen, or a demonstrable defect in a hormone biosynthetic pathway, leading to impaired thyroid hormone synthesis. It could also be due to when one or more factors impair the capacity of the thyroid to secrete active hormones sufficient to meet the needs of the peripheral tissues. The depletion of glandular organic iodine accompanying impaired hormone synthesis increases the responsiveness of thyroid structure and function to levels of TSH that remain within the normal range. When the underlying disorder is severe, compensatory responses, including hypersecretion of TSH, are inadequate to overcome the impairment, and the patient is both goitrous and hypothyroid. Thus, simple goiter cannot be clearly separated in the pathogenetic sense from goitrous hypothyroidism. Initially, goiter is characterized by diffuse, homogenous enlargement, but over time nodules often develop.

## HEALTH CONSEQUENCES OF IODINE DEFICIENCY

Iodine deficiency affects all the stages of human development starting from the fetal life (**Box 1**). If the diet of a pregnant woman lacks iodine, the fetus is also deprived of adequate iodine and, hence, cannot produce enough thyroxine. This may lead to fetal growth retardation (**Fig. 1**). Hypothyroid fetuses often perish in the womb, and many infants die within few weeks of birth. Those born with hypothyroidism have global developmental delay and remain intellectually subnormal with low IQ. They are often incapable of completing school. In areas with prevalence of mild to moderate iodine deficiency, the school children are on an average 13.5 points of IQ below those living in iodine-sufficient areas.

### BOX 1 Spectrum of iodine deficiency disorders

1. *Fetus*: Abortions, stillbirths, congenital abnormalities, neurological cretinism, mental deficiency, deaf mutism, spastic diplegia, squint myxedematous cretinism and dwarfism
2. *Neonate*: Neonatal hypothyroidism, mental deficiency
3. *Childhood and adolescence*: Goiter, hypothyroidism, dwarfism, impaired mental function, poor school performance

**Figure 1** A 3-months-old infant with hypothyroidism. Note abdominal distension, large tongue, umbilical hernia and dry skin.  
Source: PSN Menon, Anurag Bajpai.

### Effects on Growing Brain

Severe iodine deficiency during pregnancy increases risk of stillbirths, abortions and congenital abnormalities. Iodine supplementation to pregnant women in regions of severe deficiency reduces fetal and perinatal mortality and improves motor and cognitive performance of the offspring. Maternal thyroxine crosses the placenta before onset of fetal thyroid function at 10–12 weeks. The most serious adverse affect of iodine deficiency is brain damage to the fetus. The critical period for maximal brain growth and maturation comprises the last 6 months of gestation and the first year of life. Iodine is required for the synthesis of thyroid hormones, which exert action through binding of triiodothyronine (T<sub>3</sub>) to nuclear receptors. These nuclear receptors regulate the expression of specific sites in different brain regions following a precise developmental schedule. Biochemical data indicates that thyroid hormones also have an effect on RNA polymerase II in assembling messenger RNA, influence tRNA sulfurtransferase, which confers the release of polypeptide chains from ribosomes and play an important role in the timing, rate and quantity of brain cell proliferation. The growth and differentiation of the central nervous system is closely related to iodine and thyroid hormones and impairment of cerebral functions in the fetus is directly related to maternal thyroxinemia. Iodine induced hypothyroidism during the fetal period also leads to a decrease in the proportion and density of radial glial cells fibers of the hippocampal formation of the brain.

Extensive experimental studies have been done on animals to demonstrate effect of severe iodine deficiency on the brain of neonates. Postnatal morphogenesis of the nervous system in animals thyroidectomized at birth showed a decrease in axodendritic connections primarily in the neuropil, small size and abnormally densely packed perikarya and reduced number of axons and dendrites in the interperikaryonal space.

### ASSESSMENT OF IODINE DEFICIENCY

#### Total Goiter Rate

Clinically, presence of goiter (**Fig. 2**) is considered a marker of iodine deficiency. WHO staging of goiter is listed in **Box 2**. The size of the thyroid gland changes inversely in response to alterations in iodine intake, with a lag interval that varies from a few months to several years, depending on many factors. These include the severity and duration of iodine deficiency, the type and effectiveness of iodine supplementation, age, sex, and possible additional goitrogenic factors. According to WHO, total goiter rate (TGR, goiter grades 1 and 2) of 5% or more, in 6–12

**Figure 2** Goiter in a school-age child  
Source: Dr Umesh Kapil.

years school children should be utilized to signal the presence of a public health problem. The cutoff of 5% allows some margin of inaccuracy of goiter assessment and also for goiter which may occur in iodine replete population due to other causes such as goitrogens and autoimmune thyroid diseases. TGR of 5–19.9, 20–29.9, and more than or equal to 30% indicate mild, moderate, and severe endemicity of iodine deficiency.

#### BOX 2 Simplified classification of goiter\* by palpation

Grade 0	No palpable or visible goiter
Grade 1	A goiter that is palpable but not visible when the neck is in the normal position (i.e., the thyroid is not visibly enlarged). Thyroid nodules in a thyroid, which is otherwise not enlarged, fall into this category.
Grade 2	A swelling in the neck that is clearly visible when the neck is in a normal position and is consistent with an enlarged thyroid when the neck is palpated.
*A thyroid gland will be considered goitrous when each lateral lobe has a volume greater than the terminal phalanx of the thumbs of the subject being examined.	

#### 24-hour Urinary Iodine

Excretion in school-age children ( $\geq 6$  years) is considered a good marker of recent dietary iodine intake. Twenty-four-hours urinary iodine more than 100  $\mu\text{g/L}$  is a valid indicator of iodine sufficiency. About 300 casual samples of urine from a given population group provides valid estimates of iodine status in a community. Median urinary iodine less than 20, 20–49, 50–99  $\mu\text{g/L}$  indicate severe, moderate or mild iodine deficiency in a given population.

#### Thyroid-stimulating Hormone

It can serve as another marker for iodine deficiency. TSH in neonates is a valuable indicator for assessing iodine deficiency. The neonatal thyroid has a low iodine content compared to that of the adult, and hence, iodine turnover is much higher. This high turnover, which is exaggerated in iodine deficiency, requires increased stimulation by TSH. Hence, TSH levels are increased in iodine-deficient newborns in the first few weeks of life. The prevalence of neonates with elevated TSH levels is, therefore, a valuable indicator to assess the severity of iodine

deficiency in a population. Methods for determining TSH concentrations are: from either dried whole blood spots on filter paper or from serum. These methods are well established and widely available. The number of neonates with moderately elevated TSH concentrations (above 5 mIU/L whole blood) is proportional to the degree of iodine deficiency during pregnancy. When less than 3% of children show more than 5 mIU/L of TSH, this indicates iodine sufficiency in a population. Thyroglobulin reference interval for iodine-sufficient school children is 40 µg/L.

## PREVENTION

There are several modes of iodine supplementation used for prevention of IDD. These are: iodized salt, iodized oil, iodized capsules, iodized bread and iodized water. Out of these, the most effective method is iodized salt. This is because salt is one food item which is taken in a fixed amount everyday by everybody, whether rich or poor, old or young. Thus, salt is an ideal vehicle for supply of constant amount of iodine to entire population daily. It is also most economical way of supplying iodine. Public health measures to reduce IDD include measures such as universal iodization of salt, and administration of iodized oil in deficient areas. In rare instances, it may happen that salt iodization efforts are unable to meet the requirement of women during pregnancy, exposing the progeny to potential developmental risks. In such situations, while efforts to improve the salt iodization program should be continued, iodine supplementation may be considered for both pregnant women and children less than 2 years of age as a single oral dose of iodized oil every 6 to 12 months. Single oral dose of Lipiodol containing 240 mg iodine for 6-month coverage or 480 mg for 12 months is recommended.

## IN A NUTSHELL

1. Iodine is essential for normal growth and development.
2. Iodine is required in a small amount, i.e., 150 µg/day. There is no natural food item which is rich in iodine.
3. Iodine deficiency disorders include fetal loss, stillbirths, cretinism, dwarfism, intellectual disability, spastic diplegia, neonatal or childhood hypothyroidism, and poor school performance.
4. Iodine deficiency affects all the stages of human development.
5. Iodine deficiency is the world's major cause of preventable mental retardation.
6. The indicators utilized for assessment of iodine deficiency disorders (IDD) are total goiter rate, urinary iodine excretion, and thyroid stimulating hormone (TSH).
7. Iodized salt, iodized oil, iodized capsules and iodized water are common modes of iodine supplementation for prevention of IDD.

## Chapter 22.14

# Zinc in Child Health

Shashi Ajit Chiplonkar

Zinc is an essential trace mineral and a component of numerous proteins and metalloenzymes in the body which are involved in myriad of biological functions. The first cases of human zinc deficiency were reported in early 1960s in male adolescents from the Middle East as characterized by delayed sexual development and short stature. Later, efficacy of zinc supplementation was confirmed by a significant increase in height, bone development and sexual maturation.

Zinc is omnipresent in cellular metabolism. Therefore, inadequate supply is likely to have multiple biological and clinical effects. A mild to moderate deficiency of zinc may lead to retarded growth, impaired immunity and poor cognition. However, signs and symptoms of zinc deficiency are nonspecific and lack of a sensitive biomarker of zinc presents a challenge to clinicians to identify the need for medical intervention.

## EPIDEMIOLOGY

Adequacy of zinc in diet is essential to maintain a steady state as there are no specific body stores of zinc. Percent population at risk of inadequate zinc intakes is lower (6.4% to 9.6%) in Southern America, China and Europe than in Asia, North Africa, sub-Saharan Africa and west pacific countries (17.1% to 29.6%). Global estimates of zinc deficiency in pediatric population are lacking. Evidence from diet assessment studies in children indicate that the overall prevalence of zinc deficiency as 30% to 57% in children and adolescents from Asian and South African countries.

Zinc deficiency results in a substantial morbidity and mortality predominantly among children under 5 years of age who are most affected by diarrhea, malaria and pneumonia. The five countries with the highest numbers of total deaths attributable to zinc deficiency (India, Nigeria, Democratic Republic of Congo, Ethiopia and Afghanistan) together account for 47% of all attributable deaths. Zinc supplementation as an adjunctive treatment may be the best way to target children at risk of deficiency. In older children (6–16 years), zinc deficiency can lead to low immunity, stunting, impaired taste perception and poor cognitive performance.

## STRUCTURE AND METABOLISM OF ZINC

The total body zinc content is around 2 g which is found in almost all tissues and fluids. Zinc is a component of over 300 enzymes including nicotinamide adenine dinucleotide dehydrogenases, RNA and DNA polymerases, and DNA transcription factors as well as alkaline phosphatase, superoxide dismutase, and carbonic anhydrase. These are used to maintain healthy cell reproduction, growth, and adult fertility, synthesize cholesterol, protein, and fats, enhance immunity and protect the body against harmful free radicals. Zinc is vital for several body functions, such as vision, insulin function, taste perception, thymulin activity and anti-inflammatory activity. In addition, it regulates the release of vitamin A from the liver.

Zinc is important for the cognitive function of children because it is important for myelination and for release of the neurotransmitters gamma-aminobutyric acid and glutamate, which are key modulators of neuronal excitability. Zinc is an intracellular signaling molecule and it plays an important role in cell-mediated immune functions and oxidative stress. Zinc is also an anti-inflammatory agent. Zinc has direct effects on the primary hormonal system [insulin growth factor-I/growth hormone (IGF-I/GH)] that controls growth in the postnatal phase when the majority of stunting occurs.

## ABSORPTION OF ZINC

Dietary zinc is released as free ions during digestion and is actively absorbed from the gut into epithelial cells, where it is stored as mucosal metallothionein or released into the plasma, where 70% is mainly bound to albumin. It is then transported to the liver, where it is stored by hepatocytes in metallothionein. Other specific transporters, such as zinc transporter protein-1 (ZnTP-1) may facilitate passage of zinc across the basolateral membrane of the enterocyte into the portal circulation. Endogenous zinc is reabsorbed in ileum and colon creating enterohepatic circulation of zinc. Regulation of zinc absorption is thought to be controlled by the amount of metal-free albumin. Zinc is primarily stored in RBCs, WBCs, muscle, bone, skin, kidneys, liver, pancreas, retina, prostate, etc.

Increased zinc intake depresses copper absorption and conversely copper absorption is greatly increased in zinc deficiency. Metabolic interactions occur between zinc and cadmium, zinc and iron, and zinc and chromium. Cadmium and iron uptake are depressed by high zinc levels, while chromium and zinc are metabolized by a common pathway in the intestine and are mutually antagonistic.

## DIETARY SOURCES AND DAILY REQUIREMENTS OF ZINC

Animal foods like oysters, lean meat are rich sources of zinc, while plant foods contain relatively low amounts of zinc (**Table 1**). Phytic acid and fiber in these foods reduce the bioavailability of zinc. Dietary nutrients, such as iron, calcium and folic acid also affect bioavailability of zinc. Cooking processes, such as soaking, germination and fermentation of food products can reduce the inhibitory effect of phytic acid, thereby improving zinc bioavailability.

Zinc stored in body tissues does not function as zinc reserves, so the body depends on adequate dietary intake for its daily requirements. Overall, the body absorbs 15–30% of dietary zinc, depending on the body's requirement and source of zinc. Vegetarian foods have poor zinc bioavailability than animal foods. It is therefore postulated that vegetarians may have as much as a 50% higher need for zinc than non-vegetarians. The WHO has provided the recommended dietary intakes for zinc based upon levels of absorbable zinc from diets (**Table 2**).

## CAUSES OF ZINC DEFICIENCY

Inadequate dietary intake is the foremost and major contributor to zinc deficiency. It may result out of consuming foods low in zinc or

**Table 1** Zinc content of selected cooked foods per 100 g weight

Animal foods	Zinc (mg)	Plant foods	Zinc (mg)
Oysters	45.1	Pearl millet unleavened pancake	2.0
Beef lean	6.8	Lentils	1.3
Ground beef	5.8	Dill leaves	1.6
Turkey	4.2	Almonds, dry and unsalted	3.5
Chicken liver	4.0	Peanuts roasted	3.9
Shrimp	1.6	Pumpkin seeds, dry	4.2
Goat meat	5.2	Sunflower seeds, dry	5.0
Bear meat	10.2	Sesame, dry	12.2
Cheese non-fat	3.9	Cashewnuts, dry and unsalted	6.0

Source: Nutrient database for standard reference, USDA (2010), Indian cooked food database (Chiplonkar & Agte, 2007).

high in phytates or due to increased requirements during rapid growth. Malabsorption of zinc may occur in inflammatory bowel disease. Interactions with phenytoin and tetracycline reduce zinc absorption leading to zinc deficiency. Further, increased losses of endogenous zinc may occur in conditions of cystic fibrosis, celiac disease, Crohns disease, or chronic kidney disease. Diarrhea can cause zinc deficiency due to losses of endogenous zinc in diarrheal fluids.

Zinc deficiency can occur because of impaired utilization of zinc due to certain drugs (e.g., ethambutol, halogenated 8-hydroxyquinolines, penicillamine) that chelate zinc systemically and make it less available for use by tissues. Also infections cause sequestration of zinc in the liver, and decreased circulating levels of zinc, which will reduce the availability of zinc to other tissues. Over-supplementation with iron or copper has also been reported to cause zinc deficiency.

## CLINICAL MANIFESTATIONS

Growth retardation or decreased growth velocity is often the first sign of zinc deficiency in infants, children and adolescents. Severe zinc deficiency can be characterized by short stature, hypogonadism, impaired immunity, skin disorders, cognitive dysfunction, and anorexia. Although severe zinc deficiency is rare, mild-to-moderate zinc deficiency is quite common throughout the world. Clinical symptoms of zinc deficiency are illustrated in **Table 3**. Chief clinical conditions associated with increased risk of zinc deficiency are acute diarrhea, celiac disease, cystic fibrosis and Wilson disease.

Acrodermatitis enteropathica is a genetic disorder of zinc metabolism that manifests as severe zinc deficiency, characterized by failure to absorb zinc from diet, abrupt cessation of weight gain, hypogonadism, gastrointestinal disturbances and skin lesions. Skin

lesions of severe acute zinc deficiency syndromes have a characteristic distribution, primarily at the extremities and adjacent to the body orifices (**Fig. 1**). Secondary infection with *Candida* is common.

Abnormalities of immune system occur in less severe zinc deficiency also. Lowered learning abilities, apathy, lethargy, depression and mental retardation are notable features of insufficient body zinc levels.

Chronic zinc deficiency in adolescents may prolong sexual maturation. Some cases of impotence complicating chronic renal

**Table 3** Clinical features of zinc deficiency

System	Signs and symptoms
Gastrointestinal system	Loss of appetite, diarrhea, anorexia, taste and smell dysfunction, eating disorders, glossitis, gingivitis
Hair	Early graying of hair, alopecia, hair loss
Nails	Blackening of nails, nail dystrophy
Eye	Impaired vitamin A metabolism with weakened vision, eye lesions, lack of dark adaptation, photophobia, conjunctivitis, blepharitis
Central nervous system	Behavioral abnormalities, impaired mental function, cognitive dysfunction, and depressed mood
Skin	Skin lesions, acne, delayed healing of wounds, dermatitis
Reproductive system	Problems in the menstrual cycle of women, impaired reproduction, hypogonadism in males, zinc deficiency in the pregnant woman can lead to poor growth in the fetus
Growth and development	Weight loss with increased susceptibility to infections, impaired cell mediated immunity, thyroid dysfunction, growth failure, delayed sexual maturation, impaired immune function
General	Hypozincemia during fever may trigger febrile convulsions Reduced RBC zinc in patients with sub-acute thyroiditis

Manifestations depend on severity of deficiency and other factors.

disease have responded to zinc supplementation. Eye lesions that may occur in severe chronic zinc deficiency include severe photophobia and keratopathy.

## BIOMARKERS OF ZINC DEFICIENCY

A specific marker of zinc status is yet not determined owing to homeostatic control of body zinc. Levels of zinc in red blood cells, leukocytes, neutrophils and plasma or serum are some of the markers of zinc status. Clinical signs of zinc deficiency may occur when serum zinc concentrations drop below 65 µg/dL (**Table 4**). Values less than 33 µg/dL are particularly associated with loss of the senses of taste and smell, abdominal pain, diarrhea, skin rash, and loss of appetite. Other biomarkers include measurement of the activity of zinc-dependent enzymes such as carbonic anhydrase or alkaline phosphatase, urinary zinc excretion (normal range 3.3–21.4 µmol/24 hours) and hair zinc (normal range 150–240 µg/g). Functional indices such as taste acuity, cognitive ability or dark adaptation are also used to detect zinc deficiency.

## PREVENTION AND TREATMENT

Prevention and correction of zinc deficiency is vital for normalizing the function of cells in multiple tissues. It enhances the child's ability to combat disease states and not just single infectious organisms. Best preventive measure for zinc deficiency is increasing intake of foods rich in absorbable zinc. Preventive zinc supplementation is highly effective, with demonstrated benefits for pneumonia, diarrhea and growth impairment. The body requires zinc to develop and activate T-lymphocytes. Individuals with low zinc levels have shown reduced lymphocyte proliferation response to mitogens and other adverse alterations in immunity that can be corrected by zinc supplementation. Therapeutic uses of zinc are illustrated in **Table 5**.

**Table 4** Suggested lower cut-offs (2.5th percentile) for the assessment of serum zinc concentration in population studies, derived from NHANES II data

Age group	Serum zinc concentration, µg/dL (µmol/L) <sup>a</sup>		
	< 10 yrs	≥ 10 yrs	
	Children	Females (Nonpregnant)	Males
AM Fasting <sup>b</sup>	na <sup>c</sup>	70 (10.7)	74 (11.3)
AM	65 (9.9)	66 (10.1)	70 (10.7)
PM	57 (8.7)	59 (9.0)	61 (9.3)

Source: International Zinc Nutrition Consultative Group; Food Nutr Bull; 2004.

a. Conversion factor: µmol/L = µg/dL ÷ 6.54

b. Based on data from subjects 20 years and older only

c. na = not available

A meta-analysis of trials in prepubertal children indicated benefit of zinc supplement for weight and height increments, especially in underweight children and in children more than 6 months of age with evidence of stunting. Zinc supplementation also showed increased food intake in anorexia. However, loss of appetite may not be observed in zinc-deficient children having protein deficiency. Cognitive function and hedonic tone improve significantly after zinc therapy.

Recent review on preventive zinc supplementation in healthy children under five years of age showed a reduction of 13% in diarrheal morbidity and 19% reduction in pneumonia morbidity and similar reduction in mortality but no effect on malaria. A meta-analysis of zinc supplementation trials indicated reduced rate of respiratory tract infections in children.

Zinc is recommended as an additional therapy in severe malnutrition and chronic and acute diarrhea. Pooled analysis of randomized controlled trials mainly in India, Africa, South America and Southeast Asia suggest that 4–40 mg elemental zinc per day in the form of zinc acetate, zinc gluconate or zinc sulfate reduced the severity and duration of diarrheal episodes. For intravenous administration, zinc chloride is frequently used.

Acrodermatitis enteropathica appears in early infancy but with adequate zinc supplements a total recovery occurs.

Excessive intake of zinc (**Table 6**) can lead to toxic effects like nausea, vomiting, abdominal pain, diarrhea, convulsions. Chronic high dose zinc ingestion leads to lethargy, anemia, and neurological side effects predominantly due to lowering of copper levels.

## IN A NUTSHELL

1. A large percentage of the population from developing countries is affected by mild to moderate zinc deficiency.
2. Zinc supplementation is highly beneficial as a preventive measure and also as a promoter for normal growth and development.
3. Zinc is useful as adjunctive therapy in the treatment of common infectious diseases, especially diarrhea and pneumonia.
4. Adverse effects of zinc deficiency on cognitive function, taste acuity and stunting are reversible if detected and treated at an early stage.

## MORE ON THIS TOPIC

Aggarwal R, Sentz J, Miller MA. Role of zinc administration in prevention of childhood diarrhea and respiratory illnesses: A meta-analysis. *Pediatrics*. 2007;119:1120.

**Table 5** Treatment with zinc supplements\*

Condition	Zinc salt	Dose <sup>a,b</sup>
Zinc deficiency	Zinc sulfate	Full term infants and children up to 5 years 100 µg of elemental zinc/kg/day For preterm infants (up to 3 kg body weight) 300 µg of zinc/kg/day to TPN Children: 8–10 mg/day Adolescents: 15–20 mg/day
Dermatological disease	Zinc carbonate, zinc oxide and zinc chloride	Astringents
Overperspiration	Zinc hydroxybenzene sulfonate	Deodorant and antiperspirant
Eye problems	Zinc sulfate	Eye drops, oral zinc supplement
Diarrhea	Zinc sulfate	WHO and UNICEF recommend short-term zinc supplement (20 mg/day, or 10 mg for infants under 6 months, for 14 days in diarrheal diseases)
Diabetes mellitus	Zinc sulfate, zinc oxide	15–20 mg/day
Delayed growth	Zinc sulfate	Children: 8–10 mg/day Adolescents: 15–20 mg/day
Acrodermatitis enteropathica	Zinc sulfate, gluconate or other salt	Infants and toddlers: 90–130 mg/day Older children: 180–220 mg thrice daily
Wilson disease	Zinc sulfate, zinc gluconate, zinc acetate	220 mg thrice daily

\*. These are to be taken as general suggestions. Choice of zinc salt and dose may vary as per the case.

a. Zinc supplements should not be taken within 2 hours of iron, copper, calcium, folic acid or phosphate supplements.

b. Zinc supplement is usually administered 1 hour before or 2 hours after food. In the presence of gastric irritation, zinc has to be given with food.

**Table 6** Tolerable upper intake levels (ULs) for zinc<sup>a</sup>

Age	Male	Female	Pregnant	Lactating
0–6 months	4 mg	4 mg		
7–12 months	5 mg	5 mg		
1–3 years	7 mg	7 mg		
4–8 years	12 mg	12 mg		
9–13 years	23 mg	23 mg		
14–18 years	34 mg	34 mg	34 mg	34 mg
19+ years	40 mg	40 mg	40 mg	40 mg

a: The ULs do not apply to individuals receiving zinc for medical treatment and are under physician's care.

## Chapter 22.15

# Trace Elements in Nutrition and Health

P Leelakumari, KE Elizabeth

Trace elements are minerals required only in minute amounts for living organisms for normal body function and growth. They are present in concentrations less than 0.01% body dry weight. Trace element deficiencies occur commonly in children with protein-energy malnutrition (PEM), picky eaters, low birthweight (LBW) babies and those on total parenteral nutrition. Excess intake of dietary fiber, oxalates and phytates will reduce the trace element absorption. Levels of trace elements in the blood can be estimated by colorimetry, atomic absorption spectrophotometry, and neutron activation analysis. A WHO Expert Consultation has categorized nutritionally significant trace elements into three groups: (i) *Essential trace elements*: iron, iodine, zinc, selenium, copper, molybdenum, and chromium; (ii) *Elements which are probably essential*: manganese, silicon, nickel, boron, and vanadium; and (iii) *Potentially toxic elements*: fluorine, lead, cadmium, mercury, arsenic, aluminum, lithium and tin. We have already discussed iodine and zinc in detail. This chapter will deal with the rest of important trace elements. Fluorosis, a major public health problem, will be dealt in the next chapter.

## IRON

Iron deficiency is the main cause of anemia in all age groups including higher income groups. In India, two-thirds of children and women and half of men suffer from anemia. Iron is mainly used for production of hemoglobin and myoglobin. It is also a component of iron containing enzymes. Iron is available as heme iron, which is present in meat and nonheme iron found in vegetables. Heme iron is better absorbed. Fish, meat, cereals, legumes, green-leafy vegetables, dates and jiggery are good sources of iron. Cooking in iron vessels increases the iron content of food. Recommended daily amount (RDA) of iron is 10–20 mg/day. Iron deficiency anemia is detailed in Section 38 on hematological disorders.

## COPPER

Copper is widely distributed in biological tissues as organic complexes, many of which are metalloproteins. Adult human body contains 80 mg of copper with a range of 50–120 mg. Tissue copper level ranges from less than 1 mcg/g (dry weight) in many tissues to more than 10 mcg/g (dry weight) in liver and brain. Concentration of copper may be 6–10 folds greater in liver of infants during the first 2 months of postnatal life. Copper in human blood is mainly distributed between erythrocytes and plasma. In the erythrocytes, 60% of copper occurs as metalloenzymes (superoxide dismutase, cytochrome C oxidase, tyrosine oxidase), the remaining 40% being loosely bound to other proteins and amino acids. Total erythrocyte copper is 0.9–1 mcg/mL of packed red cells. In the plasma, 93% of copper is firmly bound to the enzyme ceruloplasmin and the remaining 7% is less firmly bound to albumin and amino acids.

Normal serum copper level is 0.8–1.2 mcg/mL and hypocupremia is defined as serum copper level of 0.8 mcg/mL or less (WHO) and is usually accompanied by hypoceruloplasminemia.

## Biological Functions

Copper is an essential element in human body. It is the cofactor for many enzymes, needed for hemoglobin synthesis, essential for zinc, iron and vitamin C functions, melanin synthesis, neurotransmitter synthesis, cross linkage and synthesis of elastin and collagen and central nervous system (CNS) functions.

## Dietary Sources

Good dietary sources (> 2 mcg/g) include liver, fish, oysters, organ meat, legumes, nuts and sea food. Daily requirement is 11 mcg/kg/day. The upper limit of safe range of population mean intake is 12 mg/day for males 10 mg/day for females, and 150 mcg/kg for infants (WHO). Toxicity leads to hepatic cirrhosis, hemolytic anemia, zinc deficiency and gastritis.

## Deficiency

Copper deficiency occurs in LBW and preterm babies, protein energy malnutrition and during total parenteral nutrition. Clinical features of deficiency include hypochromic anemia, neutropenia, hypopigmented hair, abnormal bone formation with skeletal fragility, osteoporosis and neurological manifestations. Metabolism of copper is deranged in Wilson's disease. Menkes kinky hair syndrome is an X-linked metabolic disturbance of copper metabolism characterized by mental retardation, abnormal hair texture, hypocupremia (< 65 mcg/dL) and low circulating ceruloplasmin (< 20 mg/dL).

## CHROMIUM

Chromium is an essential micronutrient that potentiates action of insulin and thus influences carbohydrate, lipid and protein metabolism. It facilitates weight loss and prevents diabetes. Dietary sources include yeast, liver, cereals, nuts, egg, butter and cheese. Average basal requirement of chromium is less than 20 mcg/day and the mean population intake to meet basal needs may be 25 mcg/day. Upper limit of safe range of population mean intake is 250 mcg/day (WHO).

## Deficiency and Excess

Deficiency may occur in PEM, and during total parenteral nutrition (TPN). Deficiency leads to impaired growth, elevated serum cholesterol and triglycerides, hyperglycemia, increased incidence of aortic plaques, corneal lesions and decreased fertility. Tissue chromium status may not be actually reflected by fasting plasma or serum chromium status. Serum chromium level less than 0.14–0.15 ng/mL may indicate severe chromium deficiency.

Chromium toxicity due to oral intake is rare. Toxicity usually occurs in industrial environment where concentration in the air is high or contact with skin is frequent. Toxicity leads to renal failure and dermatitis. Elevated serum chromium (> 0.15 ng/mL) is a useful indicator of excessive exposure to chromium. Another indicator is high urinary chromium level.

## SELENIUM

Selenium is a component of enzymes superoxide dismutase, glutathione peroxidase, deiodinase enzymes, thiolase and glycine reductase; and plays important role in antioxidant defense system. Selenium maintains liver integrity and helps thyroid hormone synthesis. There are many epidemiological studies on protective role of selenium against cancer. Selenium can protect against heart disease by influencing platelet aggregation. Grains, garlic, green-leafy vegetables, and meat are good dietary sources of selenium. Selenium compounds are well absorbed in humans. The rate limiting step in the overall bioavailability of dietary selenium is its

conversion within the tissues to its metabolically active form (e.g., its incorporation into glutathione peroxidase). A level of 40 µg/day is considered as the acceptable intake of selenium for Indians. The selenium content of cereals and pulses range between 30 and 400 µg/g. Safe upper limit of population mean intake of selenium for adult is 400 µg/day.

### Deficiency and Toxicity

Deficiency is common in PEM and TPN. Clinical features include myalgia, cardiomyopathy, arthritis and liver necrosis. The endemic cardiomyopathy associated with selenium deficiency is known as *Keshan disease*. It can be clinically categorized into four types as acute, subacute, chronic and insidious. Once the disease is established, selenium supplementation does not help. The major histopathological picture of the disease is multifocal myocardial necrosis. The coronary arteries are essentially unaffected. *Kashin-Beck disease* is an endemic osteoarthropathy associated with low selenium status. It occurs in children of age 5–13 years, endemic in certain regions of China. Degeneration and necrosis of hyaline cartilage lead to joint swelling and deformity.

Toxicity leads to alopecia, dental caries and a typical garlic odor in mouth. A significant handicap of research in selenium toxicity is the lack of selective and sensitive indicator of selenium overexposure in humans.

### MOLYBDENUM

The principal molybdenum containing enzymes in humans are xanthine oxidase/dehydrogenase, aldehyde oxidase and sulfite oxidase. Xanthine oxidase is involved in the conversion of purines to uric acid. Legumes and green-leafy vegetables are good sources. Animal foods except liver are poor sources of molybdenum. Plants grown in neutral or alkaline environment will be good sources and those grown in acidic medium will be poor sources.

Hexavalent molybdenum compounds are well absorbed from gastrointestinal tract (GIT). Intestinal absorption of molybdenum is inhibited by high intraluminal concentrations of sulfate anions generated by protein breakdown and oxidation of methionine and cysteine. Sulfates also reduce the tissue utilization of molybdenum and also increase the urinary excretion of molybdenum.

### Dietary Intake

Recommended dietary intake for breastfed infants is 2 µg/kg. Between weaning and 3 years of age it is 5–7 µg/kg and declines thereafter to 1.5–3 µg/kg. For adolescents and adults, the recommended dietary intake is 1.5–2.5 µg/kg. Molybdenum content of human liver is 1.3–2.9 mg/kg of dry matter and that of kidney is 1.6 mg/kg, lung 0.15 mg/kg, brain 0.14 mg/kg. Reported mean molybdenum content of human hair is 0.07–0.16 mg/kg.

### Deficiency and Toxicity

Studies in Henan Province, China suggest a high incidence of esophageal cancer with molybdenum deficiency. Other manifestations include central scotoma, irritability and coma. Molybdenum deficiency is also associated with dental caries. Molybdenum deficiency coexisting with selenium deficiency may be obligatory for the development of Keshan disease. Liver diseases, uremia, rheumatic diseases and cardiovascular diseases are associated with high serum molybdenum level.

### MANGANESE

Manganese is both an activator and a constituent of several enzymes. Manganese metalloenzymes include arginase, pyruvate

carboxylase and manganese superoxide dismutase. Manganese is essential for oxidative phosphorylation and for normal bone structure, and found mainly in bone, liver, pancreas and kidney. Rich dietary sources of manganese include unrefined cereals (wheat, barley, rice bran), nuts, leafy vegetables and tea. Average requirement is 2–5 mg/day. Indian diet rich in foods of plant origin supply an average of 8.3 mg of manganese per day, whereas highly refined hospital diets of United States supply an average of 0.63–1.78 mg/day only. Intestinal absorption is influenced by the dietary manganese content. Manganese absorption is negatively influenced by the dietary fiber content and iron.

### Deficiency and Toxicity

Manganese deficiency can lead to impaired growth, skeletal abnormalities, disturbed reproductive function, and defects in carbohydrate and lipid metabolism. Studies report low whole blood concentration of manganese in certain types of epilepsies. Whole blood manganese concentration (normal: 8.4 µg/L) is useful in assessing the status. Urinary manganese level is another indicator of its status. Activity of manganese superoxide dismutase and the ratio of manganese superoxide dismutase to copper zinc superoxide dismutase are other indicators of manganese status of humans.

Manganese is reported to be the least toxic of the trace element when administered orally. The most common form of manganese toxicity is the result of chronic inhalation of large amounts of airborne manganese in mines, steel mills and some chemical industries. The major signs of manganese toxicity in animals are depressed growth, decreased appetite, impaired iron metabolism and altered brain function. Signs of toxicity in Chilean manganese miners were first manifested in the form of severe psychiatric abnormalities, including hyperirritability, violent acts and hallucinations; these changes were called manganic madness. As the disease progressed, there was a permanent crippling neurological disorder of the extrapyramidal system with morphological lesions similar to those of Parkinson's disease.

Toxicity can also lead to cardiomyopathy, goiter and cholestasis.

### VANADIUM

Vanadium helps in regulation of enzymes Na<sup>+</sup>/K<sup>+</sup> ATPase, adenylate cyclase and protein kinase. All protein-rich foods are good sources of vanadium. Normal range of serum vanadium level is 0.016–0.939 ng/mL. Most values are less than 0.15 ng/mL. Dietary intake of 10 µg/day meets basal vanadium requirement. Daily intake of 10 mg/day can produce toxicity. Serum vanadium level more than 1 ng/mL indicates excessive exposure to vanadium.

### Deficiency and Toxicity

Deficiency can lead to skeletal and joint deformities. Vanadium is a toxic element. Toxicity leads to defective growth, loss of appetite, gastrointestinal disturbances, etc. Cardiovascular diseases are reported in few studies. Toxicity usually occurs as a result of industrial exposure to high-level airborne vanadium.

### SILICON

Silicon is the second most abundant element in the earth's crust. It is not found free in nature but occurs chiefly as the oxide and silicate. Animal experiments showed that silicon is needed for the normal development of connective tissue and bone. It helps in bone formation by facilitating the formation of glycosaminoglycans and collagen component of bone matrix. For the normal bone development in experimental animals, a requirement of 100–250 µg/g has been identified but no data are available for human

requirement. Foods of plant origin contain more silicon than that of animal origin. Whole grasses and cereals may contain 3–6% as silica. The general manifestations of silicon toxicity are collectively called silicosis. It can lead to urolithiasis.

## NICKEL

The four nickel containing enzymes found in plants and microorganisms are urease, hydrogenase, methyl coenzyme M reductase and carbon monoxide dehydrogenase. Typically, less than 10% of nickel ingested in food is absorbed. Nickel absorption is enhanced by iron deficiency. Severe deficiency leads to impairment of growth and hematopoiesis. Excess can lead to dermatitis, liver necrosis and lung cancer. Chocolate contains significant amount of nickel. Serum nickel concentrations of more than 1 µg/L indicates chronic excessive intake of nickel.

## BORON

Boron affects steroid hormone metabolism in humans and also affects major mineral metabolism in a human body. Foods of plant origin, especially fruits, leafy vegetables, nuts and legumes are rich sources of boron. Wine, cider and beer are also rich in boron. Recent studies show that 1 µg/g of dry diet meets the needs. Boron in food is rapidly absorbed in GIT and is highly excreted in urine. It is distributed throughout the tissues with the tissue concentration being 0.05–0.6 µg/g of fresh weight. The normal concentration of boron in blood is apparently between 0.1 and 0.2 mg/mL. Brain function may be affected in deficiency.

## IN A NUTSHELL

1. Most of the trace elements are essential or probably essential, but a few are potentially toxic.
2. Trace elements are required only in minute quantities and are present in selected food items.
3. Deficiency of these micronutrients causes various pathologic effects in a human body. Excess can also cause serious adverse reactions in the body. So, optimum trace element balance in body is essential.
4. Optimum trace element balance should be considered in TPN and food fortification.
5. Trace element deficiencies should be diagnosed in the early phase and corrected. Along with optimum dietary intake recommendations, factors influencing the absorption and bioavailability should be considered.

## Chapter 22.16

### Fluorosis

Sunil Kumar Gupta

Fluorine is the 13th most abundant element available in the earth crust. Fluorine, a pale yellow gas with a pungent and irritating odor, exists as a diatomic molecule with remarkably low dissociation energy. As a result it is highly reactive and has strong affinity to combine with other elements to produce compounds known as fluoride, a cause of fluorosis.

Systemic fluorosis is an endemic problem in several regions across the world including developing as well as the developed countries. WHO standards permit 1.5 mg/L and Bureau of Indian Standards (BIS) permit 1.0 mg/L as the safe limits of fluoride for human consumption. BIS 2009 further states that fluoride may be kept as low as possible. There is no RDA of fluoride for human health. Values of adequate intake (AI) are given in **Table 1**. The minimal daily fluoride intake in infants that may cause very mild or mild fluorosis is estimated to be about 0.1 mg/kg body weight.

#### EXTENT OF PROBLEM

Fluorosis is prevalent worldwide with countries like Pakistan, Bangladesh, Argentina, United States of America, Morocco, Middle East countries, Japan, South African countries, New Zealand, Thailand, etc., reporting sporadic to widespread cases. The problem has reached alarming proportions in India affecting at least 19 states out of which Andhra Pradesh, Tamil Nadu, Uttar Pradesh, Gujarat and Rajasthan are the most severely affected. People in several districts of India are consuming water with fluoride concentrations of up to 44 mg/L.

#### SOURCES OF FLUORIDE

Usually the surface water is not contaminated with fluoride, whereas ground water may contain high fluoride due to leaching of fluoride from fluoride rich rocks during the percolation of water through different strata. Minerals like fluor spar ( $\text{CaF}_2$ ), cryolite ( $\text{Na}_3\text{AlF}_6$ ) and fluorapatite  $\text{Ca}_5[\text{F}(\text{PO}_4)_3]$  also  $3\text{Ca}_3(\text{PO}_4)_2\text{CaF}_2$  or  $\text{Ca}_{10}(\text{PO}_4)_6\text{F}_2$  are found commonly in different igneous and sedimentary rocks.

Main sources of fluoride for human are water, food, air, medicament, cosmetics. Although there are several sources of fluoride intake, it is roughly estimated that 60% of the total intake is through drinking water. This is the most assimilable form of fluoride and hence the most toxic. The fluoride of food items

depends upon the fluoride content of the soil and water used for irrigation, therefore the fluoride content of the food items may vary from place to place. The available data indicate that in general the fluoride content of the various food items is as follows (given in decreasing amount of fluoride): cereals > leafy vegetables > pulses > fish > meat > fruits. Prolonged use of certain drugs has been associated with the chronic adverse effects of fluoride, e.g., sodium fluoride (now discontinued) for treatment of osteoporosis, niflumic acid for the treatment of rheumatoid arthritis, use of fluoride mouth rinses (Proflo) to render the tooth stronger. The use of fluorides in industry can also lead to occupational exposure, e.g., inorganic fluoride compounds are released in air during the production of aluminum as well as phosphate fertilizers.

Highly significant associations have been found between estimated fluoride ingestion from fluoridated toothpaste and fluorosis. In the fluoridated brands, there is a deliberate addition of fluoride, which may range from 1,000 mg/L to 4,000 mg/L (ppm). Apart from the available drinking water supply, the bottled mineral water may also be a source of excessive fluoride ingestion.

#### CHEMOBIOKINETICS AND METABOLISM (FLOW CHART 1)

Ingested fluoride is rapidly absorbed through gastrointestinal tract and lungs. The peaks are reached after 30 min in blood. The rapid excretion takes place through renal system over a period of 4–6 hour. In children less than 3 years of age only about 50% of total absorbed amount is excreted, but in adults and children over 3 years—about 90% is excreted. Approximately 90% of the fluoride retained in the body is deposited in the skeleton and teeth. The biological half-life of bound fluoride is several years. Transplacental passage of fluoride has also been reported. Fluoride also excreted in low concentrations in saliva, sweat, and milk.

#### PATHOPHYSIOLOGY

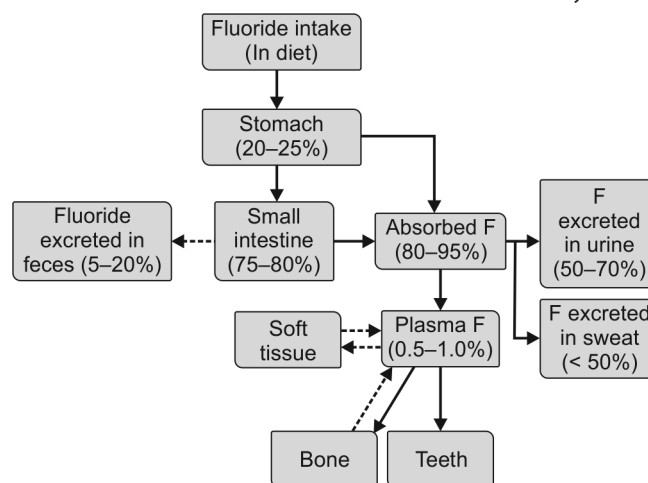

Ingestion of fluoride causes decrease in the ionized calcium. Resultant hypocalcemia causes secondary hyperparathyroidism, leading to increased activity of osteoclasts in bone by activating membrane bound 3'5' cyclic adenosine monophosphate (AMP). This increased osteoclastic activity causes increase in citric acid and lactic acid release from ruffled border of osteoclasts, increasing hydrogen ion concentration, and hence lysis of lysosomes. Release of lysosomal enzymes *viz.* acid protease, collagenase, hyaluronidase in bone and other tissues of the body, catalyze the reactions favoring the depolymerization of the glycoprotein of bone and of cartilage. This causes breakdown of hydroxyproline, which is

**Table 1** Adequate intake (AI) for fluoride (mg/day)

Life stage	Age	Males (mg/day)	Females (mg/day)
Infants	0–6 months	0.01	0.01
Infants	7–12 months	0.5	0.5
Children	1–3 years	0.7	0.7
Children	4–8 years	1.0	1.0
Children	9–13 years	2.0	2.0
Adolescents	14–18 years	3.0	3.0
Adults	19 years and older	4.0	3.0
Pregnancy	All ages	-	3.0
Breastfeeding	All ages	-	3.0

Source: Harrison's Principles of Internal Medicine; 2012. pp. 590–91.

**Flow chart 1** Metabolism of fluoride in human body

responsible for stabilization of collagen triple helix. As the protein polymer desegregates and dissolves, the mineral-binding capacity is also reduced and calcium is liberated, which helps in maintaining the serum calcium level. As a result the solubility of hydroxyapatite crystals also increases, causing its breakdown, along with reduced laying down of collagen by reducing hydroxylation of proline and lysine. This event simultaneously leads to elevation of GAG (glycosaminoglycans) (seromucoid). The net result of degradation of ground substance [collagen fibers, GAG (proteoglycans and glycoprotein)] in bones, tendons, muscles, and other calcified tissues like teeth leads to symptoms of fluorosis (**Flow chart 2**).

Elevated content of GAG in bone and its reflection in serum is considered as an index to assess fluoride toxicity and fluorosis at very early stages. The ratio of N-acetyl neuraminic acid in serum [serum sialic acid (SSA)] to GAG is a sensitive index to detect fluoride toxicity at very early stages both in human and animal models. The ratio of SSA/GAG revealed a 30–50% reduction in human sera in fluoride poisoning. Serum alkaline phosphatase (SAP) activity is high in fluorosis, indicating increased osteoblastic activity. Both mature and immature osteoblasts are increased and secrete more osteocalcin.

## DETERMINANTS OF THE DISEASE

Chronic fluoride exposure and the biological response leading to ill-effects depend on the following factors: concentration of fluoride in drinking water, food, and cosmetics; low calcium and high alkalinity of drinking water; age of the individual; duration of intake; pregnancy, lactating mother; derangement in hormonal profile either as a result of fluoride ingestion or cause, aggravates the disease. The affected hormones are calcitonin, parathyroid, vitamin D and cortisol, necessary for healthy bone formation and bone function.

## CLINICAL PRESENTATION

### Acute Fluoride Intoxication

Initial symptoms are nonspecific and include diffuse abdominal pain, diarrhea, vomiting, excessive salivation with thirst, perspiration and painful spasms in the limbs. Later on the clinical presentation are related to derangement of enzyme systems such as those engaged in metabolism, energetic, and cellular respiration and in endocrine functions. Symptoms particularly relate to alimentary, cardiovascular, respiratory and central nervous systems. The acute lethal dose of fluoride for man is probably about 5 g as NaF. Death occurs in 2–3 days.

### Management of Acute Toxicity

Monitor and support vital signs, cardiac monitoring for arrhythmia, treat them especially in the presence of refractory hyperkalemia. Gastric lavage, if emesis has not occurred. Charcoal is probably not of benefit. Monitor serum electrolyte, calcium, and magnesium levels and treat accordingly. Administer milk, oral calcium salts, or aluminum or magnesium based antacids to bind fluoride. Consider hemodialysis if required.

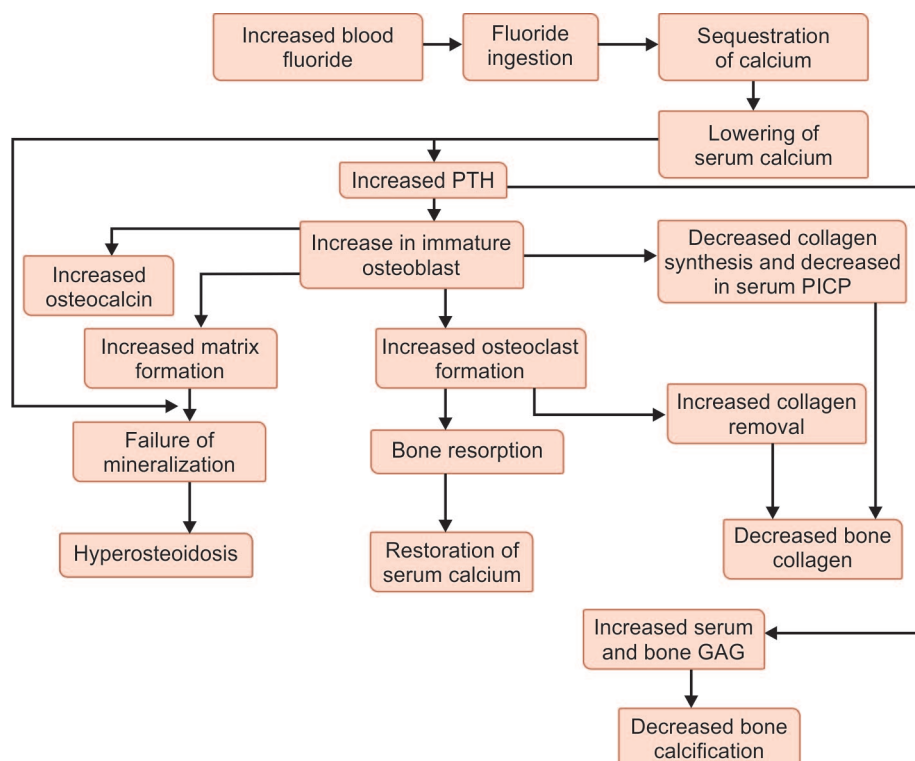

### Chronic Fluoride Ingestion

Toxic effects manifests as skeletal or dental fluorosis, or non-skeletal manifestations, including premature aging.

### Dental Fluorosis

Features vary and include the following: white opacities, faint to dark yellow stain, pitting, chipped off edges, black discoloration, enamel hypoplasia, delayed eruption, and edentate (loss of teeth at an early age) (**Figs 1A and B**). Incidence of mottled teeth was observed even with range of 0.7–1.5 mg F/L in drinking water.

**Flow chart 2** Pathophysiology of fluorosis

**Figures 1A and B** (A) Dental fluorosis: grade 4 (Photograph indicating discrete or confluent pitting. Brown stains are widespread, and teeth presenting corroded like appearance); (B) Enamel hypoplasia (Fluoride induced)

The minimal daily fluoride intake in infants that may cause very mild or mild fluorosis in human beings was estimated to be about 0.1 mg/kg body weight.

#### *Skeletal Fluorosis*

Pain and stiffness in joints results in an arthritis type picture; pain and stiffness in back causes restriction of movement of the skin. Stiffness spreads and may present as discomfort and paresthesia in limbs and trunk. Poker Back sign is a late presentation. Joint deformity is a late presentation. The commonly involved joints are knee, hip, spine, etc. Exostosis in long bones may be apparently visible.

#### *Clinical Fluorosis*

Fluorosis presents as heel pain, knock knee, painful and restricted joint movements, deformities in limbs, hunch back (**Figs 2A to C**) and in extreme cases with paralysis, muscular wasting and premature aging.

#### **Systemic Manifestations**

**Neurological** Nervousness and depression, tingling sensation in fingers and toes, polydipsia and polyurea, headache.

**Gastrointestinal** Dyspepsia, acute abdominal pain, diarrhea, constipation, melena.

**Muscular** Muscle weakness and stiffness, pain in the muscle and loss of muscle power.

**Allergic** Very painful skin rashes (pinkish red or bluish red spot, round or oval shape), due to perivascular inflammation. The rashes fade and clear up within 7–10 days.

**Red blood cells** Excessive fluoride accumulates on the erythrocyte membrane, causing loss of calcium content. This results and is formation of echinocytes. The life span of these echinocytes is less causing early destruction, leading to anemia.

**Ligaments and blood** Ligaments tend to harden and calcify and the blood vessels get blocked.

**Figures 2A to C** Clinical fluorosis: (A) Deformity of leg; (B) Knock knee; (C) Hunch back

**Fertility** Fluoride reduces fertility by decreasing Leydig cell function, testosterone levels and spermatogenesis. It also disturbs the sertoli cell function.

**In utero exposure** High fluoride exposure during pregnancy causes intrauterine growth retardation and effects primary dentition in infant.

**Mental efficiency** Excessive fluoride intake reduces mental work capacity and hair zinc content. In animal studies it is reported to cause decreased 5-hydroxyindoleacetic acid and increased norepinephrine in brain.

**Thyroid** Fluoride has inhibitory effect on iodine uptake. Goiter prevalence is more in fluoride prone areas.

**Others** Excess fluoride may have an association with certain neoplasms, may impair glucose tolerance, and inhibit lactation.

## DIAGNOSIS

Clinical examination, examination of teeth and three simple clinical diagnostic tests described in **Figure 3** are generally followed for the initial diagnosis of the problem. Biochemical evaluation includes estimation of serum calcium; serum alkaline phosphatase; fluoride levels in whole blood, serum and urine; ascorbic acid levels in serum and leukocyte; serum parathyroid hormone; serum sialic acid and serum GAG. Bone fluoride content is increased in fluorosis.

## Radiological Evaluation

Involvement of the axial skeleton is characteristic, and changes are most marked in the spine (**Figs 4A to D**), pelvis and ribs. Radiographs reveal osteosclerosis, periosteal bone formation; calcification of interosseous membrane, ligaments, capsules, muscular attachments, tendons, exostoses; and osteophytosis. In early fluorosis osteosclerosis and thickening at the junctions of trabeculae is observed. Interosseous membrane calcification in forearm (**Figs 4A to D**) and calcification of the sacrotuberous ligament is considered a characteristic feature. In children skiagram of long bones are also helpful, which are characterized by osteopenia and bony deformities (**Figs 5A and B**).

## Bone Scintigraphy

Metabolic superscan on skeletal scintigraphy reveals increased tracer uptake in axial and appendicular skeleton, reduced soft tissue uptake, poor or absent renal images, prominent costochondral junction and *tie sign* in sternum. These findings are indicative of high bone turnover state in endemic skeletal fluorosis.

## CT Examination

Plain CT scan reveals increased bone density (osteosclerosis), osteopenia, osteoporosis, trabecular blurring or haziness, compact bone thickening, periosteal bone formation and ossification of the attachments of tendons, ligaments, and muscles. Interosseous membrane calcification and ossification of the posterior longitudinal ligament can also be visualized. Syndesmophytes (calcification or heterotopic ossification inside a spinal ligament or of the annulus fibrosus) may be present.

## MRI

The findings reported include vertebral sclerosis, encroachment and narrowing of neural foramina and, in some cases a combination of premature degeneration with anterior disc herniation, lateral disc herniation leading to indentation of thecal sac and narrowing of neural foramina, and generalized iliac wings sclerosis.

**Figures 3A to C** Clinical tests for diagnosis of fluorosis. (A) Normal person can touch the toes with fingers. Fluorosed person cannot bend without folding his knees; (B) Normal person can touch the chest with chin. Fluorosed person cannot touch the chest with chin; (C) Normal person can fold the arms and touch the back of the head. Fluorosed person cannot fold the arms and touch the back of the head

## DIFFERENTIAL DIAGNOSIS

### Dental Fluorosis

Dental fluorosis should be differentiated from dental caries. The pitting, chipping and discoloration occurs on incisal edge and occlusal surface (biting surface) of teeth, whereas in fluorosis, these changes occur on labial surface of teeth initially and later on extending to incisal edge and occlusal surface also. Fluoride dental stains, which are internal stain and very difficult to remove (decolorize), should be differentiated from external stains caused due to eating of fruits and stain of brinjal, banana, and tetracycline. Pyorrhea and halitosis should not be confused with dental fluorosis.

### Skeletal Fluorosis

Fluorosis need to be differentiated from rickets, renal osteodystrophy and other congenital malformations. Urinary and serum fluoride levels, radiographs of skeletal, calcification of the interosseous

membranes in the forearm and sclerosis of the vertebral column will clinch the diagnosis. Joint pains in skeletal fluorosis (arthritic presentation) have to be differentiated from those caused by osteoarthritis, rheumatoid arthritis, and ankylosing spondylitis,

etc. If required, bone biopsy for estimation of fluoride content of bone provides conclusive evidence. In later stages skeletal fluorosis is marked by restriction of spine movements. Increased sclerosis of spine on radiography will confirm the diagnosis.

### Nonskeletal Fluorosis

The preskeletal stage of fluoride intoxication poses problems for diagnosis. In these cases radiograph of the skeleton will neither show sclerosis or calcification of the ligaments nor significant elevation of urinary levels of fluoride. Moreover, the manifested symptoms are so varied that they may be identifiable with those of various other diseases. The complaints of the victims in this regard are so common place that they may be easily mistaken for those resulting from other ailments, e.g., dyspepsia, musculoskeletal pain, headache, etc.

## TREATMENT AND PREVENTION

### Treatment

Vitamins C and D, and, salts of calcium, were prescribed in an attempt to reverse the effects of fluorosis. Latest studies indicated that fluorosis could be reversed partially, at least in children by a therapeutic regimen of calcium, vitamin C and vitamin D supplementation. Calcium in gut directly inhibits the absorption of fluoride ions, improves the serum calcium levels, inhibits the excessive release of parathyroid hormone thereby preventing excessive activation of osteoblasts and osteoclasts and hence preventing hyperosteoidosis and osteopenia. Calcium also helps in bones and teeth mineralization.

Calcium should be given as recommended dietary allowance (RDA) plus 25 mg elemental calcium per mg of fluoride for neutralizing excessive fluoride intake. Vitamin D<sub>3</sub> (60,000 IU once or twice a week) enhances calcium absorption and retention without causing hypercalcemia. Ascorbic acid (500–1000 mg/day) controls collagen formation and hence maintains the teeth and bone structure. It provides the conditions favorable for laying down of collagen, improving the hydroxylation of proline. Calcium and vitamin C should be supplemented at different time to avoid development of conditions favorable for formation of renal stones. For stained and disfigured teeth, cosmetic dental treatment is advised.

### Prevention

Providing defluoridated water for drinking purpose is the best way to prevent fluorosis. Many methods based on precipitation, adsorption, ion exchange, electrochemical and membrane processes have been developed in the past few decades to remove fluoride from drinking water. Two commonly used field defluoridation techniques in India are Nalgonda process and activated alumina process. In these processes aluminum compounds are used for removal of fluoride from water. Apart from removal of fluoride these processes result in moderate to high residual aluminum in treated water, creating a predisposing condition for formation of aluminofluoride complexes. Aluminofluoride complexes are of grave health concern due to their neurotoxicity mediated through stimulation of various guanine nucleotide binding proteins (G Proteins).

Fluorosis can also be mitigating by effecting minor changes in the diet and dietary habits of the population compatible with their social system and available resources. The main aim should be to restrict use of fluoride rich food; avoid use of fluoride rich cosmetics; and use of food rich in calcium, vitamin C and proteins. Rainwater storage can be a major source of fluoride free drinking water for both humans as well as animals. A hygienic storage of rain water for ingestion can help relieve the fluorosis problem to a good extent.

**IN A NUTSHELL**

1. Fluorosis affects mainly bone and teeth but practically affects all systems of body.
2. Fluoride ingestion should be avoided in pregnant and lactating mother.
3. It is possible to revert the fluorosis presentations partially at least in children by medical management (calcium, vitamin D and vitamin C supplementation).
4. Avoiding f-rich food (especially tea and fluoridated tooth-paste) and use of food rich in calcium and vitamin C are highly effective, both as treatment measure in children and preventive measure to all ages.
5. Defluoridation of water is an effective way of disease prevention.

## Chapter 22.17

# Enteral and Parenteral Nutrition

Ashish Bavdekar

Nutritional support refers to enteral or parenteral provision of calories, protein, electrolytes, trace elements, vitamins, minerals along with sufficient fluids. The word *enteral* means *through the gastrointestinal tract* and any route other than the gut which is used for nutrient delivery into the body is referred to as *parenteral*. The basic goal of nutrition support is to meet the metabolic needs of the child in order to mitigate the breakdown of muscle protein and to provide substrate for the anabolic state during recovery.

All efforts should be made in hospitalized children to detect malnutrition at an early stage. Patients should be considered malnourished or at risk of developing malnutrition if they have inadequate nutrient intake for 7 days or if they have a weight loss of 10% or more of their preillness body weight. Patients who cannot maintain adequate oral intake are candidates for nutritional support and should be considered for enteral feeding first. Enteral nutrition (EN) and parenteral nutrition (PN) should be combined when enteral support alone is not possible. When administering nutrients enterally, access to the gastrointestinal tract should be gained in the most natural and least invasive manner. The parenteral route needs to be used only when the patient is at risk for malnutrition due to poor oral intake, where a trial of enteral feeding has failed, or where severely diminished intestinal function due to underlying diseases or treatment is anticipated. Choosing the enteral or parenteral route requires knowledge of their advantages and disadvantages. The advantages of enteral nutrition are: (i) preserves gastrointestinal (GI) structure and function, gut hormonal response, normal gut flora, normal blood supply to the gut, and the integrity of gut-associated lymphoid tissue (GALT); (ii) it may help prevent bacterial translocation and sepsis; (iii) complications are far lesser than PN; and (iv) EN is far less expensive than PN. The advantages of parenteral nutrition are (i) no risk of aspiration of tube feeding; (ii) better patient acceptance; (iii) more reliable delivery; and (iv) it is the only method of nutrition in severe intestinal failure.

## ENTERAL NUTRITION

Enteral nutrition is defined as delivery of food directly into stomach or duodenum or jejunum over tube or stoma or/and oral provision of dietary foods for special medical purposes.

### Indications

- To provide nutritional requirements which cannot be met by regular food intake in a patient with at least a partially functional gut (**Table 1**).
- As treatment of specific diseases—Crohn's disease and food intolerance, etc.
- In a neurologically impaired child, if feeding times are excessive.

### Contraindications

**Absolute contraindications** include intestinal perforation, necrotizing enterocolitis, bowel obstruction or ileus, inability to access the GI tract—trauma, burns, or significant hemodynamic instability. Relative contraindications (in these situations, EN should be given as much as tolerated and the remaining requirement completed by PN) include intractable vomiting or diarrhea; acute abdominal distention; high output gastric, enteric fistula; severe upper gastrointestinal bleeding; and intestinal dysmotility.

### Enteral Formulations

Enteral formulations should supply an adequate intake of nutrients in a form and volume that the child can tolerate. Enteral feeds supply

**Table 1** Indications for enteral nutrition

Inadequate intake	Sucking/swallowing disorders – preterm babies, neurologic impaired children Congenital abnormalities of upper GI tract—to fistula Local problems—trauma, extensive facial burns Critical illness with impaired oral intake—on ventilation Severe GE reflux
GI disorders	Exocrine pancreatic insufficiency—cystic fibrosis Inflammatory bowel disease Malabsorption syndrome—food allergy, severe celiac disease Intractable diarrhea of infancy Severe immunodeficiency Chronic liver disease with malnutrition Chronic pseudo-obstruction Extensive intestinal disease
Other indications	Chronic organ diseases, heart, kidneys Disease management, Crohn's disease, glycogen storage disease

a balanced mix of all of the essential nutrients needed for meeting physiological requirements and growth. Most enteral formulations can be used as a sole source of nutrition for prolonged periods of time. They usually have an energy density of 1 kcal/mL and can be delivered via tube but may also be taken orally. Feeds with a higher energy density (1.5 kcal/mL) are useful in children with increased energy requirements. Enteral formulations are usually gluten free, lactose free or low lactose and iso-osmolar (300–350 mOsm/kg). While selecting an appropriate formula, one should consider the site, route and mode of delivery. It is individualized according to patients' nutritional needs and the underlying clinical condition. Standard enteral formulations are either polymeric, semi-elemental or elemental (**Table 2**). Polymeric formulas meet the requirements of most pediatric conditions and are generally effective in the presence of an intact bowel. Polymeric preparations are easily available in India, semi-elemental with some difficulty and pure elemental preparations have to be procured from abroad.

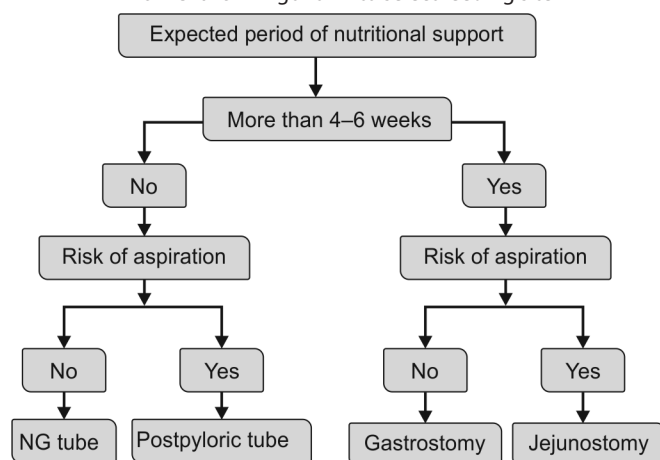

Besides the standard formulae, the following specialized formulae are also available for specific indications: (a) MCT enriched formulas for fat malabsorption disorders; (b) high caloric formula (1.5 kcal/mL) for conditions where fluid restriction is required, e.g., renal failure; (c) immunomodulating formula with glutamine, omega-3 fatty acids, nucleotides; and branch chain amino acid formula for liver disorders.

### Site and Mode of Delivery

Enteral nutrition can be administered either into the stomach or beyond the pylorus, depending on the morphology and function of the GI tract and the risk of aspiration of gastric contents. Whenever possible, gastric feeding is selected as it is more physiological, easier to achieve secure positioning, associated with flexible feeding schedules, tolerance of volume and hyperosmolar solutions because of the reservoir capacity of the stomach, lower frequency of diarrhea and dumping syndrome. Gastric acidity also has an antibacterial function. Postpyloric feeding is indicated only in clinical conditions in which aspiration, gastroparesis, pyloric obstruction, or previous gastric surgery precludes gastric feeding or when early postoperative feeding after major abdominal surgery is planned. If the expected duration of feeding is short (< 6–8 weeks), feeding can be delivered by nasogastric or nasoenteric feeding tube. But if the expected duration is more than 6–8 weeks, a feeding gastrostomy or jejunostomy is recommended (**Flow chart 1**). Polyvinyl chloride (PVC) tubes are less desirable because they can release potentially toxic phthalate esters into fat-containing feedings and need to be changed every 3–5 days as they become rigid. Silicone

**Table 2** Enteral formulations

	<i>Polymeric</i>	<i>Semi-elemental</i>	<i>Elemental</i>
Nitrogen source	Whole proteins	Small peptides	Amino acids
Carbohydrate source	Glucose polymers	Glucose polymers	Glucose polymers
Fat source	LCT or LCT + MCT	LCT + MCT	LCT + MCT
Caloric density	1–2 kcal/mL	1–1.7 kcal/mL	0.67–1 kcal/mL
Osmolality	300 mOsm/kg	300–450 mOsm/kg	300–600 mOsm/kg
Advantages	Palatable, relatively inexpensive	Hypoallergenic, easily absorbed	Nonallergenic, immunomodulatory
Disadvantages	Requires intact GI tract	Bad taste, expensive	Some are expensive, hyperosmolar, bad taste
Indications	Multiple	Allergy, malabsorption	Multiple allergies, severe malabsorption

**Flow chart 1** Algorithm to select feeding site

and polyurethane tubes can usually be safely kept in place for up to 8 weeks. Feeding tube diameter is selected according to the weight and age of the child. The smallest external diameter possible should be used because it causes less patient discomfort than larger tubes. *The required length of the tube is the distance between the nose and the umbilicus.*

Intermittent bolus feedings consist of fixed volumes of feeding delivered several times daily usually every 1–3 hour. If well tolerated, intermittent gastric feeding is preferred because it is more physiological, they elicit cyclical surges of trophic GI hormones, are less expensive and less restrictive. Continuous feeding is the continual delivery of feeding over 12–24 hour. Usually a feeding pump is used to regulate feeding delivery. There is very limited data to suggest that continuous feed is better tolerated compared to bolus feeds, except maybe in patients with severely impaired GI function where continuous feeding might be beneficial. On the other hand, continuous enteral feeding is associated with impaired gallbladder emptying in infants. A constant infusion of nutrients at less than 3 kcal/min is required to prevent delayed gastric emptying and vomiting. Postpyloric feeding needs to be continuous and should be increased cautiously, particularly when hyperosmolar feeds are used as it may lead to dumping syndrome. When the child can eat, both methods of feed delivery can be combined by tube feeding overnight for 10–12 hours and oral intake during the day. This combination is particularly beneficial for the preservation of sensory and motor oral functions.

### Complications of Enteral Feeding

Though much safer than PN, enteral tube feeding may be poorly tolerated and does carry some risks (**Table 3**). Refeeding syndrome

is discussed below. Long-term tube feeding is associated with failure to develop (or regression of) oromotor feeding skills.

### Refeeding Syndrome

Various metabolic complications can arise as a result of providing enteral/parenteral nutritional feeding to malnourished patients. During prolonged fasting, energy is derived from fats by generating ketones and there is suppressed insulin secretion and increased glucagon secretion. Sudden reversal of catabolism through nutritional support (particularly excessive carbohydrate) leads to a surge of insulin secretion, which causes massive intracellular shift of phosphate, magnesium, and potassium with a subsequent fall in serum concentrations. Glucose and levels of the B vitamins thiamine may also fall. This causes hemolytic anemia, muscle weakness, and impaired cardiac function which could lead to cardiac failure, fluid overload, arrhythmia, and death. The risk is greatest in the first week of feeding. To prevent this syndrome, it is important to gradually increase the volume, protein and energy content of feeds, and supplement vitamins and electrolytes (especially phosphorus) during nutritional repletion.

### Monitoring Enteral Nutrition

Children receiving enteral nutrition should be monitored regularly to assess growth, fluid, energy and nutrient intake, therapeutic efficacy, and to prevent complications. Biochemical monitoring and assessment of acute weight changes are keys to preventing metabolic complications. The most common metabolic complications are electrolyte abnormalities, alteration in fluid status and hyper- and hypoglycemia. Clinical observations and assessment of intake and output help prevent development of GI complications. The most common complication is diarrhea. Vomiting, abdominal distension and pain, and constipation may also occur. Growth and development are key indicators of tube-feeding efficacy. Psychological aspects should be monitored to prevent problems such as feeding aversion and loss of feeding skills. Despite the broad range of possible complications, enteral nutrition is a relatively safe and effective way of improving nutritional status, clinical condition and growth of pediatric patients, particularly if procedural protocols are followed and regular quality control is applied.

### PARENTERAL NUTRITION

In a number of illnesses (both surgical and medical), the nutritional demands of the child cannot be met adequately through the enteral route for prolonged periods. The concept of providing all the required nutrients like proteins, carbohydrates, fats and vitamins via the intravenous route, is called parenteral nutrition. The advent of successful PN has indeed reversed the prognosis of

**Table 3** Enteral feeding complications and preventive and therapeutic measures

Complications	Cause	Prevention/Treatment
Diarrhea	Unsuitable feed in a child with impaired gut function	Change to semi-elemental/elemental feed
	Excessive feeding	Give more frequent smaller feeds, or change to continuous feeds
	Intolerance of bolus feeds	Change to iso-osmolar feeds or slowly increase feed concentration, try continuous infusion
	High feed osmolarity	Prepare feeds in hygienic environment
Nausea/vomiting	Microbial contamination of feed	
	Excessive feeding	Reduce volume and rate and increase slowly as tolerated
Regurgitation/aspiration	Slow gastric emptying	Encourage lying on right side. Give prokinetics
	Gastroesophageal reflux	Correct positioning, feed thickener, drugs, continuous feeds, postpyloric feeding, fundoplication
	Dislodged tube	Secure tube adequately and regularly review position
	Intolerance of bolus feeds	Smaller, more frequent feeds or continuous infusion

many such illnesses, which were hitherto fatal. The popularity of PN is now fast growing in our country too, despite the constraints of cost and infrastructure. Although widespread availability is very much desired, it is important that the technique is developed with considerable expertise and used judiciously with full knowledge of its indications, limits, dangers and benefits.

### Indications

Parenteral nutrition should be used only if EN cannot be used for any reason. PN is required in any situation in which the baby should not be fed, will not feed, or cannot be fed adequately for prolonged periods. It is usually indicated when there is bowel dysfunction resulting in inability to tolerate EN for more than 1–3 days in infants and 4–5 days in older children. Other deciding factors are underlying malnutrition, nature of concurrent therapeutic measures (e.g., ventilation) and the expected outcome of the disease. In the Indian setup, social and monetary background is also an important consideration. The range of indications of PN has grown considerably in recent years. Some common indications are discussed below:

#### Surgical Conditions

Parenteral nutrition has dramatically changed the outcome in extensive resections of the small intestine, enterocutaneous fistulae and short gut syndromes. The most gratifying results with PN are in surgical neonates with successful surgical correction, e.g., tracheoesophageal fistula, duodenal atresia, omphalocele, and Hirschsprung disease. The need for PN in such conditions can be predicted early and therapy can be started immediately after corrective surgery.

#### Low Birthweight Infants (LBWs)

The numerous feeding difficulties, the poor intestinal function, and the greatly increased requirements make PN a logical choice in preterms less than 28–32 weeks gestation and/or less than 1,000 g. It is also indicated in newborns who are unlikely to achieve at least 50% enteral feeds by day 5.

#### Malabsorption Syndromes

One of the commonest indications for PN has been severe persistent diarrhea in children irrespective of the etiology: infectious diarrhea, congenital enteropathies, or immune deficiency. The recent use of special enteral diets has definitely reduced the need of PN in these cases. However, due to unavailability of these diets in India, there is still an important role of PN in these conditions. Disorders with severe small intestinal mucosal pathology (e.g., microvillus inclusion disease) often require long-term PN as gastrointestinal losses of fluids, electrolytes and proteins continue even after stopping all enteral feedings. A judicious combination of enteral and parenteral nutrition will obviously allow restoration of normal nutritional status while maintaining gastrointestinal function.

### Nongastrointestinal Indications

An increasingly common indication of PN today is in management of children with malignant diseases, as chemotherapy and radiation may impair intestinal mucosa, damage circulatory vessels and lymphocytes and interfere in gastrointestinal motility. PN is also increasingly used in a host of other conditions such as end stage liver disease (pre/post-liver transplants), renal failure (with appropriate amino acids) and multiple trauma or extensive burns (to combat excessive nitrogen losses).

### Nutrient Sources

The basic solutions comprise a protein source, a lipid source, and a carbohydrate source to be mixed with electrolytes, vitamins and trace metals, all appropriate to the age, body weight and energy requirements of the child.

#### Proteins

These solutions are mixtures of crystalline amino acids (AA), at least 40% of which are essential amino acids. Neonates and young infants are particularly sensitive to imbalance in amino acid solutions. They need conditional amino acids like histidine, cysteine and taurine. Amino acid requirements are given in **Table 4**. Caution should be exercised while using AA solutions primarily designed for adults.

#### Lipids

Parenteral lipid emulsions are concentrated sources of calories and are available in 10% or 20% strengths. In children only 20% is used providing 2 kcal/mL. Being isotonic and low in osmotic activity, lipids can be given through peripheral veins for prolonged periods. Lipid emulsions are available as soy, fish oil or SMOF (soybean oil, MCTs, Olive oil, Fish oil). Lipids are started in dose of 1 g/kg/day up to a maximum of 2–3 g/kg/day.

#### Carbohydrates

Glucose is the carbohydrate of choice, as it is an energy substitute with ubiquitous utilization by all tissues of the body. It typically provides 40–55% of caloric intake. The monohydrate form provides 3.4 kcal/g. Glucose substitutes such as sorbitol, fructose, and xylitol, have also been tried although they are metabolized only in the liver and tend to cause osmotic diuresis.

#### Electrolytes, Vitamins, Minerals and Trace Elements

Daily estimated requirements of electrolytes, vitamins and minerals (Na, K, Ca, P, Mg) must be added to PN. There are limitations to the amount of calcium and phosphorus that can be supplied as they can precipitate in PN solutions. Intravenous preparation for phosphorus is not easily available in India and has to be supplied orally.

## Other Components

Heparin in doses of 0.5–1.0 U/mL may be added to the PN solution to prevent thrombophlebitis and stimulate lipoprotein lipase. Insulin may be added for maintaining sugar levels in patients with hyperglycemia.

## PN Assembly and Regimens

The route of providing PN is either by central venous access (tip of catheter is in superior or inferior vena cava or right atrium) or peripheral venous access. The central access is preferred if PN is to be given more than 2 weeks, if peripheral access is poor, if patient is fluid restricted and hypertonic solutions have to be used (osmolality > 900–1,000 mOsmol/L). Traditionally PN solutions are two-in-one solutions with the IV lipid administered separately. This is used in many hospitals since it allows for the easy identification of precipitates and for increased electrolyte administration. The three-in-one solutions have the amino acids, glucose and lipids mixed together and are usually administered at home for ease of care, but are also being used in some pediatric hospitals. In India small volume three-in-one solutions are not available and hence cannot be used in small children. Filters are placed in line between the PN solution and the patient and are very important. A 0.22 micron filter is used for the two-in-one solution to remove most pathogenic bacteria (For three-in-one solutions, a 1.2 micron filter is used which removes only *Candida* and large lipid droplets).

Parenteral nutrition is introduced gradually over a period of 2–4 days depending on size and age of child. The calculated quantities of amino acids, dextrose and electrolytes are mixed in the same bottle under laminar air flow. This mixture and the lipid emulsion are administered by separate IV sets and the two lines coupled by a Y connector just before entry into the vein. Both the solutions should be regulated by infusion pumps to provide accurate steady flow rates. Progressive build up regimens for neonates, infants and older children have been described (Table 4). Enteral feeds should be started as soon as possible in trophic amounts. Once enteral feeds are tolerated, PN is weaned off. PN should not be decreased until enteral feeds exceed 50 mL/kg/day. However, do not exceed total (enteral + parenteral) proteins 3.5 g/kg/day and fat 5 g/kg/day. Stop PN when third fourth of daily enteral intake has been achieved.

## Complications

### Technical

Central venous access has potential arterial hemorrhage, air embolism and cardiac arrhythmias. Complications of peripheral access include thrombosis, perforation of vein, with necrosis of tissue, and thrombophlebitis. Nonthrombotic occlusions are caused by calcium phosphate precipitates, medication precipitates, lipid residue, or mineral precipitates. The use of 0.1N hydrochloric acid is most effective for clearing catheter occlusions due to precipitation of calcium-phosphate. For catheter occlusions due to precipitates associated with medications in the high pH range such as tobramycin and phenytoin, sodium bicarbonate 1 mEq/mL has been anecdotally reported to be effective. 70% ethanol is the most effective solvent to dissolve lipid residue.

**Table 4** Amino acid requirement in parenteral nutrition (g/kg/day)

Preterm infants	1.5–4.0
Term neonates	2.0–3.5
Child 5–20 kg	1.0–2.5
20–40 kg	1.0–2.0
Adolescent	0.8–2.0

## Infections

Sepsis associated with PN is life-threatening. Sources are multiple and include entry site of catheter, connections, PN fluid, etc. There is a need to differentiate between a central line infection and colonization. About 22% of all hubs are colonized with bacteria. Infections may be difficult to recognize as some patients may be febrile only during PN infusions or when the central line is flushed. A white blood cell count may be normal in circumstances where the infection is at the exit site. The common organisms are *Staphylococcus epidermis*, *S. aureus* and occasionally gram-negative and fungal sepsis. Therapy is determined by the organism involved and antibiotic sensitivity. Strict asepsis during catheter insertion, preparation and administration of PN, use of laminar flow system and training of staff dealing with PN can go a long way in reduction of sepsis. Tubing for lipids should be changed every 12–24 hours and the dextrose tubing be changed every 72 hours unless it is a three-in-one solution.

## Metabolic

- Complications of protein metabolism** The use of crystalline amino acids has significantly reduced the risk of hyperammonemia. Amino acid infusion may have to be reduced till ammonia levels normalize. Metabolic acidosis is more frequent when a large infusion of amino acids is given to preterm infants.
- Complications of carbohydrate metabolism** Hyperglycemia is usually a problem in central venous administration when dextrose is delivered directly into the central venous flow. Other causes to be considered are hypokalemia, sepsis and steroid use. Hyperglycemia could lead to glycosuria, osmotic diuresis and dehydration.
- Complications of fat metabolism** Hypertriglyceridemia and high free fatty acid levels are associated with PN. These can be prevented by either using mixed solution of MCT and LCT or regular monitoring of serum triglyceride levels.
- Complications related to electrolytes and minerals** Hyponatremia, hypo/hyperkalemia hypocalcemia, hypomagnesemia and hypophosphatemia are commonly associated with PN. These are often iatrogenic and preventable by monitoring. Trace element and vitamin deficiencies are common on long-term PN. They need to be supplemented especially in LBW infants.

## Hepatobiliary Complications

These appear in 40–60% of neonates and 10–15% of older children on PN, and include steatosis, cholestasis, cholelithiasis, fibrosis or cirrhosis. The cause is multifactorial and involves duration of PN, LBW, associated trophic enteral feeds, sepsis, remaining bowel length in surgical resections, type of amino acid and lipid solutions used. Treatment includes starting at least minimal EN if possible, starting cyclical PN, reducing dose of lipids and using fish oil based emulsions and adding ursodeoxycholic acid.

The fear of PN related complications has always been a deterrent in the institution of this potentially life-saving technique. However, the complication rates in our unit have shown a marked decline with intensive and continuous training of staff, especially the resident doctors and nurses. Especially designed, locally manufactured intravenous sets, use of a laminar flow workstation for compounding and other such adaptations have contributed further. The most significant reductions occurred in local complications, such as thrombophlebitis from 89% in 1986 to 29.4% in 1991 and septicemia from 52% to 11.7%.

## Monitoring

Meticulous monitoring is necessary not only to detect complications, but to document clinical benefit. Most septic and

metabolic complications can be prevented or detected before they cause serious consequences, if the biochemical monitoring protocol is followed rigidly. Monitoring should be more frequent in the initial stages of PN and perhaps, less frequent once PN is well established. The monitoring protocol at our hospital is given in **Table 5**. It is mandatory to develop micromethod systems for biochemical monitoring in newborns and young infants. In absence of these, blood sampling volumes should be carefully recorded and replenished when indicated. Adjustments in daily electrolytes, nutrients and fluid orders are based on biochemical monitoring.

### Cost Analyses

Parenteral nutrition is expensive and quite often methods are devised locally to save costs. This is perfectly acceptable as long as care is taken to ensure that these measures do not affect the safety of the patient. Cost saving may be achieved by (i) reducing wastage by sharing solutions between patients and preventing over-prescription; (ii) decreasing complications by using peripheral lines, preventing metabolic complications, and strict asepsis; and (iii) Indigenization of equipment for delivery of PN. A reduction in cost should not be attempted by repeated use of same PN solutions over days; compromise on biochemical monitoring, disposables, or compromise on infusion pumps; and substituting hypertonic glucose for lipids as source of energy.

**Table 5** Suggested monitoring protocol for parenteral nutrition

Serum electrolytes	3 times/week initially, then weekly
Serum urea nitrogen	3 times/week initially, then weekly
Calcium, magnesium, phosphorous	3 times/week initially, then weekly
Glucose	2 times/day
Serum proteins	Weekly
Liver function tests	Weekly
Hematocrit	Weekly
Urine glucose	Daily
Serum triglycerides	4 hour after a dose increase of lipids initially, then weekly

### IN A NUTSHELL

1. Nutrition support plays an important role in the management of hospitalized children.
2. Use the gut for enteral nutrition (EN) whenever possible.
3. Standard polymeric formulations are effective in most patients.
4. Gastric feeding should be preferred over transpyloric feeding whenever possible.
5. Parenteral nutrition (PN) is lifesaving in some conditions where EN is not possible.
6. Strict monitoring is required to prevent and treat complications in PN.
7. Regimens for PN differ in children and small preterms.

## Chapter 22.18

# Nutrition in the 21st Century

Gouri Rao Passi, Piyush Gupta

What are our children eating today? Has the pattern changed? Will these changes have lasting implications on their health? Do we need to do anything about it? And what can we possibly do? These are questions which we all need to ask, whether we are parents, pediatricians, health activists or government policy makers. Because, it seems obvious, that the market economy, the media, our changing patterns of work and social structure have made deep and lasting alterations in the eating patterns of children.

### GROWING PRESENCE OF PROCESSED FOOD

July 1991 marked the beginning of globalization in India. Many transnational corporations entered India, resulting in an explosive growth in the food processing industry and affected the nutritional habits of Indians children and adolescents. Increasing incomes shifted food patterns away from cereals. The ubiquity of television and powerful hold of the media on public imagination also caused the inevitable shift towards increasing intake of processed foods and a penchant for fast foods. According to the National Restaurant Association of India (NRAI) 2010 report, the fast food industry in India is currently estimated to be, growing at a compound annual growth rate of 35–40%. The majority comprises of global players (McDonald, KFC, Pizza Hut, etc.) but domestic players (Nirula, Haldiram, and others) are not lagging behind.

Urban India has witnessed a marginal decrease in consumption of rice and wheat and increase in milk and egg intake. What is more worrisome is a widespread increased intake of tea, biscuits, salted snacks, prepared sweets, edible oils, sugar and jaggery with a parallel decline in the intake of fruit and vegetables. Diets have shifted towards more sugars and fats, less fruit and fewer vegetables. The desired focus on intake of nutritive (cereals) and protective foods (fruits) is lacking. Approximately 95% of Indians have diets deficient in fruit (below the ICMR norm). Vegetable intake appears adequate in all expenditure classes (100–300 g/day), however a significant proportion is contributed by tubers (potato, in particular). These are rich in carbohydrates, leaving the diets inadequate in green and yellow vegetables. Intake of soft drinks, biscuits, processed foods, salted snacks, prepared sweets and other purchased foods constitutes 100–427 (average 167) g/capita/day. They may add up to 50% of the required calories per day in the high-income classes.

### FAST FOOD AND JUNK FOOD

#### Junk Food

Junk food is defined as *any food, which is low in essential nutrients and high in calories and sodium. They contain little or no proteins, vitamins, or minerals; but are rich in salt, sugar, fats, and calories.*

#### Fast Food

*Fast food* refers to food which can be prepared and served quickly and includes chips, sandwiches, burgers, french fries, chicken nuggets, pizza, or ice cream. Fast-foods are usually processed and prepared in an industrial fashion. Over the past half century, both nationally and internationally, expansion of fast food companies has been in close parallel with the obesity epidemic. The United States now has approximately 250,000 fast food restaurants, and total fast food consumption has risen from 2% to 10% of total energy intake per person over a 20-year period. Surveys have

revealed that the top 3 reasons US consumers choose fast food over healthier alternatives are: fast food is quick (92% of respondents), restaurants are easy to visit (80%), and the food tastes good (69%).

#### Nutritive Value of Fast Foods

An occasional meal in a fast food restaurant will probably not have major implications. But teenagers consuming these foods daily need to carefully consider their nutritional impact. A typical meal in a fast food restaurant (consisting of burger, french-fries, and milk shake) may furnish about 50% of the daily caloric requirement of a teenage boy, 40% or more of the protein allowance, and up to one-third of his thiamin, riboflavin, and niacin allowances. It also provides significant amounts of calcium and iron. But if the milk is replaced with coffee or a soft drink the calcium content of the meal goes down. Most fast food meals are low in fiber, vitamins A and C and some trace minerals.

Fast food as children's meals first made their entry in the late 1970s. They are extremely popular with toddlers and adolescents. In nutritional terms, fast food children's meals are rich in total fat and trans fats, have high caloric density, and low nutritional value. A recent study observed that barely 3% of the fast food children's meals meet the standard criteria for healthy meals. Eating away from home, specifically consumption of fast food, is a risk factor for childhood obesity. A study in school going children of 10–17 years old in Lucknow (2011) showed that more than 50% consumed fast foods more than 3 times a week. A significant correlation was observed between consumption of fast food and obesity/overweight. A strong positive correlation has also been observed between visits to fast food restaurants and weight gain with insulin's resistance. The specific aspect of fast food consumption that contributes most to obesity and insulin resistance is possibly higher amounts of industrially produced *trans fatty acids* (TFAs). Transisomers of fatty acids are formed by the partial hydrogenation of vegetable oils to produce margarine and vegetable shortening. They contain increased ratios of plasma low-density-lipoprotein to high-density-lipoprotein cholesterol. Intake of foods that are major sources of transisomers of fatty acids (margarine, cookies, cake, and white bread) are significantly associated with higher risks of coronary heart disease. In the United States, an average daily intake of 5 g of TFAs has been estimated to increase an individual's risk of heart disease by 25%. A child meal at a fast food outlet can have up to twice this amount of trans-fat. Another aspect of fast foods which contribute to obesity is the increasing size of portions being marketed by fast food companies.

Fast foods also have a high salt content. A study of salt content in the 22 junk food samples in India was in the range 0.2–4.2 g per 100 g of sample. The highest salt content was found in instant noodles. WHO recommends salt intake of less than 5 g per person per day for the prevention of cardiovascular disease.

### SUGAR SWEETENED BEVERAGES

Sugar-sweetened beverages (SSBs) are drinks sweetened with sugar, high-fructose corn syrup, or other caloric sweeteners. The term soft drink includes sodas along with other sugar-sweetened beverages such as fruit drinks, fruitades (drinks made by adding water to powder or crystals), lemonade, and iced tea. The term soda means sugar-sweetened carbonated beverages such as colas. These are one of the largest sources of nondietary (empty) sugars for urban children and adolescents. A child can gain around 200 kcal from one can of soda due to 40 g of sugar in it. The sugar is usually high fructose corn syrup (HFCS) which is 45% sucrose and 55% fructose. Added to a normal diet, this can cause a weight gain of 6–7 kg in a year. A systematic review published in 2006 (30 studies) has clearly documented a positive correlation between the intake of sugar sweetened beverages and obesity. Fructose contributes to greater

weight gain by enhancing lipogenesis by increased production of triacylglycerols and reducing production of insulin and leptin in peripheral tissues. It needs to be seen whether high fructose corn syrup is more detrimental than other sugars or not. Intake of sweetened sodas has also been linked to with an increased risk for the development of type 2 diabetes. Increased intake of caffeine in sodas (10–16 mg/100 g) is also associated with increase in blood pressure of adolescents. Other problems associated with colas are increased risk of dental caries, decrease in nutritious liquids like milk and an increased risk of fractures due to abnormal calcium phosphorus ratios due to high phosphate content.

### Fruit Juice and Fruit Drinks

American Academy of Pediatrics (AAP) defines *fruit juice* as either natural or 100% concentrate without added sweeteners. Anything less than 100% concentrate is labeled as drink, beverage, or cocktail. *Fruit drinks* are defined as calorically sweetened beverages with a small percentage of fruit juice or juice flavoring containing carbonated water. *Fruit drinks* have less than 20% concentrate and *nectars* have around 20–99% concentrate. Sometimes, fortifiers such as vitamin C or calcium are also added to the fruit drinks. Fruits and 100% juices contain water, simple carbohydrates (sucrose, fructose, glucose, sorbitol), high amount of vitamins (C, A) and minerals (potassium, calcium etc.). However fruit drinks, even 100% juice is not equivalent to whole fruits. Fruits supply fibers and phytochemicals to diet, which are not present in juices. Fruit juice robs the child of opportunities to learn skills like peeling, chewing, and differentiating between colors, textures and shapes. Fruit drinks, thought to be complete source of energy, vitamins and minerals are actually a mere sweet drinks and poor source of nutrition. Whole fruits are less calorogenic as compared to fruit juices and fruit drinks.

### Energy Drinks

These are nonalcoholic beverages containing stimulants like caffeine, herbal extracts (guarana, ginseng, yerba mate, ginkgo biloba), glucuronolactone, taurine, inositol, L-carnitine and B-vitamins as the main ingredients, besides having carbohydrates, to enhance physical and mental endurance. Energy drinks are consumed to improve the stamina and energy levels before and during exercise, to rehydrate the body, to keep awake in demanding situations, to compensate for loss of sleep especially during exams, or to get a kick as a mood elevator by mixing it with alcohol. The main constituent of energy drink is caffeine; up to 80 mg per serve. Natural caffeinated beverages including coffee, cocoa, tea, and cola drinks are not regarded as energy drinks.

Energy drinks are widely consumed by adolescents as they claim to improve performance, endurance and alertness. Recent reports have shown that apart from brief caffeine high, there are no real health benefits of these drinks. Their excess can be harmful. Intake of energy drinks prior to physical activities may be undertaken while keeping their possible deleterious effects in mind. Their use during physical activity is not recommended.

### ORGANIC FOOD

Organic foods are grown without application of synthetic fertilizers, pesticides, fumigants (containing nitrogen or other heavy metals), human excreta, growth hormones, or genetically engineered techniques. The land on which they are grown has to be free of any of these prohibited substances for at least 3 years, before organic crop is grown. Organic animal products (milk, egg, chicken, meat, etc.) are produced from animals fed on 100% organic food for at least 12 months.

Organic foods are said to be rich in antioxidants, phenolics, vitamins A, C and E, potassium, phosphorus, nitrates, Omega-3

fatty acids, and alpha linoleic acid (ALA). Worthington reported higher levels of vitamin C, iron, magnesium and phosphorus, lower quantities of proteins though of better quality, lesser nitrates and lesser amount of heavy metals in crops produced by organic farming system. A recent meta-analysis has shown higher concentrations of protein, ALA, total omega-3 fatty acid, cis-9, trans-11 conjugated linoleic acid, trans-11 vaccenic acid, eicosapentaenoic acid, and docosapentanoic acid in organic dairy products. Purported advantages of organic foods include lower risks of eczema and pesticide exposure but it is counterbalanced by fears of increased risks of bacterial contamination, aflatoxins and heavy metals.

Organic foods are claimed to be pesticide free and promoted as superior and safer options for today's health-conscious consumer. However, scientific data, proving the actual health benefits of organic foods, especially in children is lacking. The Indian Government has developed strict guidelines and certification procedures to keep a check on manufacturers for this financially attractive market with a certification scheme having a logo "India Organic". The American Academy of Pediatrics in its recently issued guidelines did not recommend organic foods over conventional food for children.

### FOOD CONTAMINATION

A variety of inorganic and organic chemical substances (xenobiotics) may contaminate the food chain during production, storage, processing, preparation or distribution before the food is consumed. Some of these contaminants are naturally occurring and others are man-made chemical substances such as fertilizers and pesticides. These substances are now recognized as major ecological and health risks.

### Natural Toxins

A peculiar type of progressive spastic paraplegia (lathyrism) occurring in some parts of Central India is attributed to consumption of a legume. *Lathyrus sativum*, commonly known as *khesari dal*, is used by poor people in this area. The toxic substance responsible for the neurological lesions is identified as an unusual amino acid, *Beta-diamino-propionic acid*. *Lathyrus sativum* is a hardy, drought resistant crop, which gives a high yield with minimum of agricultural inputs. It is a rich source of vegetable proteins. Its use for periods longer than 3–6 months may cause crippling manifestations of neurolathyrism with insidious onset and protracted course.

Cotton seeds are known to contain a toxic-polyphenolic pigment called *gossypol*, which binds lysine and prevents release of this essential amino acid, thus impairing the nutritional quality of cotton-seed protein. Gossypol also causes anorexia, diarrhea, hemolysis, hypoprothrombinemia, gastrointestinal hemorrhages and pulmonary edema. Seeds of some toxic weeds, which grow along with the cereal crops, get mixed up with the latter at the time of harvesting. These contain toxic alkaloids which may cause minor gastrointestinal illness or at times more serious manifestations such as veno-occlusive disease. Other toxic substances include trypsin inhibitors in green peas and aconite beans, and phytohemagglutinin in red kidney beans.

### Bacterial Toxins

These toxins are produced by bacteria such as *Clostridium perfringens* and *C. botulinum* or fungi (molds) such as aflatoxin from *Aspergillus flavus* and unidentified mycotoxins in pearl and finger millets. Mycotoxins are the most potent natural toxins responsible for human health risks. These toxic metabolites are produced by fungi infesting foodstuffs, especially cereals and nuts, which have been stored under conditions of elevated temperature and high humidity. Mycotoxins of importance in India include aflatoxin, fumonisins, trichothecenes, ergot alkaloids

and ochratoxins. The ICMR multicenter study on the occurrence of aflatoxin contamination in risk commodities namely, maize and groundnut showed that 21% of groundnut samples and 26% of maize samples analyzed exceeded Indian tolerance limits of 30 µg/kg. Presence of microbial agents such as *Salmonella*, *Shigella*, *Staphylococci*, *E. coli* and *B. cereus* in the food may cause severe life-threatening illness.

### Pesticides

Pesticides may be obtained from natural sources, such as nicotine, *Pyrethrum* and rotenone or these may be of synthetic chemical origin. The latter are broadly classified under three groups, viz., organochlorine compounds, organophosphorus compounds and carbamates with recent introduction of some new agents such as dioxin and chlorodimeform. In some countries, salts of copper are still being used for crop protection. *Organochlorine compounds* like DDT, chlordane, heptachlor, aldrin, dieldrin, benzene hexachloride (BHC) and endosulfan, persist in the environment for a considerable time. They are fat-soluble and easily enter the food chain. They mostly affect the nervous system, with manifestations such as hypersensitivity, excitability, convulsions and paralysis. They have also been linked with hematological malignancies. *Organophosphorus compounds* are easily biodegraded and do not accumulate in animal tissues. These act by inhibiting the enzyme cholinesterase. Toxic symptoms include increase in the pulse rate, excessive salivation, sweating, muscle tremors, convulsions and coma. Death may occur due to asphyxia. Other chemical contaminants include nitrosamines which are formed from nitrates and nitrites (such as those used in curing meats) and are carcinogenic in animals and heavy metals like lead, iodine, mercury, zinc, arsenic, copper, and selenium which are found in varying quantities in foods.

### Accidental Contamination

Water seeping through the soil which is rich in chemicals such as fluorides causes epidemic fluorosis in certain regions of the country. Discharge of industrial chemical effluents in rivers leads to chemical intoxication of food. Accidental suction of sewage in water supply system may cause widespread epidemics of hepatitis and other enteric infections. And a very large amount of arsenic has been observed in ground water, in Bangladesh and Bengal. Prolonged boiling of milk in untinned copper vessels was suspected to be a cause of Indian Childhood Cirrhosis, which has become rare due to change in habits and switching over to stainless steel utensils for cooking. Mixing of seeds or fava beans with food may cause severe hemolysis in individuals with glucose-6-phosphate dehydrogenase deficiency.

Food is adulterated by mixing (a) spices with colored salts of lead and other heavy metals, (b) food and spices with nonedible substances, (c) mustard oil with oil of *Argemone mexicana*, which causes epidemic dropsy, (d) cooking oil with aviation lubricant which caused the Moroccan tragedy—paralysis occurring in consumers of this spurious cooking oil containing ortho tricresyl phosphate.

### POSSIBLE INTERVENTIONS

Interventions to promote healthy food habits include media and education campaigns, labeling and consumer information, taxation, subsidies, and other economic incentives; school and workplace approaches; local environmental changes; and direct restrictions and mandates.

### Media

Several focused media campaigns have been conducted to increase knowledge about and consumption of specific healthy

foods. A variety of media have been used, including television, radio, print, or billboard advertising; in-store media education; and leaflets mailed or delivered door-to-door. In America “5-A-Day For Better Health!” campaign to increase consumption of fruits and vegetables to at least 5 servings a day, was initiated by the National Cancer Institute with collaboration from industry and the federal government.

### Nutritional Labeling

Labeling the nutritional value of foods both on packaged foods and on menu cards has been proposed as a method to allow consumers to make informed choices. Labeling should include calories, added sugar, total fat, trans fat, saturated fat, sodium and protein content.

### Legislation

On January 21, 2011, WHO formally issued a recommendation asking for a ban on junk food in schools and playgrounds in order to promote healthy diet and tackle child obesity. UK banned junk food in schools in 2005. A ban on junk food ads during television programs aimed at children below 16 years came into force in August 2008. Denmark imposed a fat tax on junk food in October 2011. In India according to FSSAI, junk food is not defined, but instead calls within the category of proprietary food—which is food not standardized under regulations. This category of food is only expected to declare their composition or nature of food and comply with general regulations under the food act. In March 2003, Denmark became the first country to restrict the use of TFAs in food products. And in 2006, the New York City Department of Health and Mental Hygiene put forth a bold proposal to eliminate all artificial TFAs from restaurant food. Food contamination can be reduced by banning production and sale of dangerous pesticides as has been done in various nations.

### Economic Incentives

There have been many attempts to increase use of healthy foods and restrict junk food by using economic incentives. These include lowering costs of healthy foods, increasing taxation on high calorie beverages, changing taxation and subsidies to encourage agricultural growth of vegetables and fruits over animal and dairy products.

#### IN A NUTSHELL

1. Child should be offered a plate filled with plenty of brightly colored vegetables, fruits and sprouts.
2. Ice cream, chocolates and other heavy desserts can be replaced by low fat fresh yogurt.
3. Fresh lime juice, coconut water and fresh fruit juices should be preferred to sodas and soft drinks as beverages.
4. Prefer grilled fresh sandwiches to fried ones. Similarly, when choosing the meat or poultry select baked, broiled, grilled items rather than fried ones.
5. Avoid giving chocolate bars as gifts or reward to the children for their good habits or academic achievements.
6. Limit the portion size of the food ordered. Regular size meal may be opted against ‘mega meal offer’ or ‘combo meal offer’.
7. While eating away from home, avoid opting for dishes with rich creamy layers and lots of spices.
8. Replace *naan* with *tandoori roti* as low fat option breads in Indian menu.
9. Dishes can be stir fried rather than deep fry to decrease the fat content.
10. Dough used for preparing *poori/pakor*as should be thick and avoid using *ghee* or oil for making the dough as this might increase oil absorption.

## Chapter 22.19

# National Nutrition Programs

Dipty Jain, Veena Kamat, Vinit Warthe

The problem of malnutrition in India has been recognized since inception of Five Year Plans and a number of nutrition programs have been introduced for combating it. These programs were initially started as a short-term emergency measure and were by no means expected to eradicate the problem of nutritional disorders from country. However, they have been effective to some extent in reducing the quantum of severe form of nutritional disorders and associated morbidity and mortality.

## THE NATIONAL NUTRITION POLICY

Government of India adopted the National Nutrition Policy in 1993 in view of widespread malnutrition and its effect on health. The National Plan of Action on Nutrition was developed in 1995. The goals of National Nutrition Policy are highlighted in **Box 1**.

### BOX 1 Goals of the National Nutritional Policy

- Reduction in the incidence of moderate and severe malnutrition and stunted growth among children by half.
- Reduction of incidence of low birthweight babies to less than 10%.
- Elimination of blindness due to vitamin A deficiency.
- Reduction in iron deficiency anemia among pregnant women to 25%.
- Universal iodization of salt for reduction of iodine deficiency disorders to below endemic level of 10%.
- Production of 250 million tonnes of food grains annually.
- Promoting appropriate diets and healthy lifestyle.

The policy highlights the importance of direct nutrition interventions for vulnerable groups as short-term measures; and long-term institutional and structural changes, to create conditions for improved nutrition. These are listed below:

### Short-term Measures

- Nutrition intervention for especially vulnerable groups.
- Program for 0–6 year children, mothers, and adolescent girls, e.g., Integrated Child Development Service (ICDS).
- *Fortification of essential foods* Salt with iodine and or iron, vitamin A, and fat with vitamin A.
- Control of micronutrient deficiency amongst vulnerable group, e.g., vitamin A prophylaxis, National Nutritional Anemia Prophylaxis Program.
- Popularization of low-cost nutrition foods.

### Long-term Institutional and Structural Changes

Long-term institutional and structural changes are aimed at improving food production, improvement of dietary pattern through production of nutritionally rich foods, improving purchasing power for food, strengthening the public distribution system, implementing land reforms, imparting basic health and nutrition knowledge, prevention of food adulteration, developing a system of nutrition surveillance, monitoring of nutrition programs, and promoting research for various aspects of nutrition.

## NUTRITION PROGRAMS

The Government of India has initiated several large scale feeding programs aimed at supplementing the nutrition and overcoming specific deficiency diseases. Recently Government has notified the National Food Security Act, 2013 on 10th September, 2013 with

the objective to provide for food and nutritional security in human life cycle approach, by ensuring access to adequate quantity of quality food at affordable prices to people to live a life with dignity. A number of programs were implemented in the past with some degree of success and some failures. Some of these programs are briefly described below:

### Special Nutrition Program

It was launched in the country in 1970, by the Ministry of Social Welfare. It was initiated for the benefit of children less than 6 years of age, pregnant and nursing mothers. The program was taken up in rural areas, tribal areas and slums. The supplementary food under this program supplied about 300 kcal and 10–12 g of protein per child per day and 500 kcal and 25 g of protein for a pregnant woman per day. The supplementary food was supplied six days per week. The aim was to cover the calorie gap between the recommended and actual intakes in low-income families.

Wheat Based Supplementary Nutrition Program was introduced in 1986. This program follows the norms of Special Nutrition Program or of the nutrition component of ICDS. It consists of supply of free wheat and supportive costs for other ingredients, cooking, transport, etc.

### Balwadi Nutrition Program

It was launched in 1970 by the Ministry of Social Welfare. The target age group was children aged 3–6 years. The program was implemented through *Balwadis*. Four national level organizations including the Indian Council of Child Welfare were given grants to implement the program. It provided 300 calories and 10 g of protein per child (3–5 years) per day for 270 days a year.

### Applied Nutrition Program

It was introduced as a pilot project in Odisha in 1963. It was later extended to Tamil Nadu and Uttar Pradesh. The objectives of the program were to promote production of fruits and vegetables and to ensure their consumption by pregnant woman, nursing mothers and children. Nutritional education was one of the main components of the program. The goal was to teach rural communities through demonstration how to produce food for their own consumption. The beneficiaries were children aged 2–6 years, pregnant woman and lactating mothers. Nutrition worth 25 paise per child per day and 50 paise per woman per day was provided 52 days in a year. The objective of the program was to provide better seeds and encourage kitchen gardens, poultry farming, beehive keeping, etc.

### Integrated Child Development Service Scheme

Integrated Child Development Service scheme was launched on 2nd October, 1975 (5th Five year Plan) in pursuance of the National Policy for Children in 33 experimental blocks. Later, the goal was for universalization of ICDS throughout the country. The primary responsibility for the implementation of the program is with the Department of Women and Child Development, Ministry of Human Resources Development at the Center and the nodal departments at the state which may be Social Welfare, Rural Development, Tribal Welfare, Health and Family Welfare or Women and Child Development. Beneficiaries included children below 6 years; pregnant and lactating women; women in the age group of 15–44 years; and adolescent girls in selected blocks. Objectives are listed in **Box 2**. The package of services provided by ICDS included supplementary nutrition to children below 6 years and pregnant women; immunization; health check-ups; referral services; treatment of minor illnesses; nutrition and health education to women; preschool education of children in the age group of 3–6 years; and convergence of other supportive services like water supply and sanitation.

**BOX 2 Objectives of ICDS**

- Improve the nutrition and health status of children in the age group of 0–6 years.
- Lay the foundation for proper psychological, physical and social development of the child.
- Effective coordination and implementation of policy among the various departments.
- Enhance the capability of the mother to look after the normal health and nutrition needs through proper nutrition and health education.

Supplementary nutrition aims to provide 500 kcal and 12–15 g protein per day to children between 6 months and 6 years; 800 kcal and 20–25 g proteins per day to severely malnourished children; and 600 kcal and 18–20 g of protein to pregnant women per day. For children below 3 years the food is given as a *take home ration*. Growth monitoring and nutrition surveillance are also done in the *anganwadis*. Children below the age of three years of age are weighed once a month and children between 3 and 6 years of age are weighed quarterly. Weight-for-age growth cards are maintained for all children below six years. This helps to detect growth faltering and helps in assessing nutritional status. Besides, severely malnourished children are given special supplementary feeding and referred to medical services. Recently, teenage clinics and adolescent care and counseling are also being integrated into this program.

**Scheme for Adolescent Girls (Kishori Shakti Yojna)**

There was a gap in between women and child age group which was not covered by any health and social welfare program whereas girls in this crucial group need special attention. On one side they need appropriate nutrition, education, health education, training for adulthood, training for acquiring skills as the base for earning an independent livelihood, training for motherhood, etc. Similarly on the other side their potential to be a good community leader has to be realized. A scheme for adolescent girls was launched by the Department of Women and Child Development, Ministry of Human Resource Development in 1991. All adolescent girls in the age group of 11–18 years (70%) received the following common services: watch over menarche, immunization, general health check-ups once in every 6-month, training for minor ailments, deworming, prophylactic measures against anemia, goiter, vitamin A deficiency, and referral to PHC, district hospital in case of acute need.

**Mid-day Meal Scheme**

To enhance school enrollment, retention, attendance and simultaneously improve nutritional levels among children, the National Program of Nutritional Support to Primary Education (NP-NSPE) was launched as a Centrally Sponsored Scheme on 15th August 1995. In September 2004 the scheme was revised to provide cooked mid-day meal with 300 calories and 8–12 g of protein to all children studying in classes I–V in Government and aided schools. In October 2007, the scheme has been further revised to cover children in upper primary classes VI to VIII.

Objectives is to improve the nutritional status of children in classes I–VIII; and encouraging poor children, belonging to disadvantaged sections, to attend school more regularly. To achieve these objectives, a cooked mid-day meal with the following nutritional content is provided to all eligible children (**Table 1**). The programs aim to provide 1/3 of the energy and ½ of the overall protein requirements.

The Central Government supplies the full requirement of food grains for the program free of cost. For its implementation in rural areas, *Panchayats* and *Nagarpalikas* are also involved or setting up of necessary infrastructure for preparing cooked food. For this

purpose NGOs, women's group and parent-teacher councils can be utilized. The total charges for cooking, supervision and kitchen are eligible for assistance under Poverty Alleviation Program. In several states, supplementary feeding was assisted by food supplies from Cooperation for American Relief Everywhere (CARE) and World Food Program (WFP). There are problems of administration and quality of food that have affected the program outcomes.

**Table 1** Nutritional content provided by a cooked mid-day meal to all eligible children

Components	Primary	Upper primary
Calories	450 kcal/day/child	700 kcal/day/child
Protein	12 g/day/child	20 g/day/child
Micronutrients	Adequate quantities of iron, folic acid and vitamin A	

**Vitamin A Prophylaxis Program**

The program was launched in 1970 with the objective of reducing the disease and preventing blindness due to vitamin A deficiency. The strategy consisted of administration of prophylactic vitamin A as per the following dosage schedule: 100,000 IU at 9 months with measles immunization, 200,000 IU at 16–18 months, with DPT booster, and then 200,000 IU every 6 months, up to the age of 5 years. Other components include health and nutrition education to encourage colostrum feeding, exclusive breastfeeding for the first six months, introduction of complementary feeding thereafter and adequate intake of vitamin A rich foods, and early detection and proper treatment of infections

**National Nutritional Anemia Prophylaxis Program**

The program was launched in 1970 run by Maternal and Child Health (MCH) Division of Ministry of Health and Family Welfare. The objective was to prevent nutritional anemia in mothers and children. The program is now extended to adults and adolescents.

**Strategies**

- The pregnant (expectant), nursing mothers and acceptors of family planning are given 100 mg of elemental iron and 0.5 mg of folic acid tablets for 100 days.
- Children (6 months–5 years) given 20 mg of elementary iron (60 mg of ferrous sulphate) and 0.1 mg (100 mg) of folic acid per mL in liquid formulation for 100 days.
- School children (6–10 years) given 30 mg of elemental iron and 250 mg of folic acid for 100 days.
- Adolescents (11–19 years) are given 100 mg of elemental iron and 0.5 mg of folic acid tablets for 100 days on priority basis.
- Multiple channels and strategies like double fortified salts/sprinklers/ultra-rice are required to address the problem of iron deficiency anemia.
- New strategies to be tried are use of traditional food processing techniques to increase bioavailability of iron; improve dietary behavior through nutrition education; and consume iron-fortified processed complementary foods.

**National Iodine Deficiency Disorders (IDD)****Control Program**

National Goiter Control Program, launched in 1962, was renamed as National Iodine Deficiency Disorders Control Program (NIDDCP) in 1992. The goal was to reduce prevalence of iodine deficiency disorders below 10% in entire country by 2012 AD. The objective included conduct of surveys to assess the magnitude of Iodine deficiency disorders in the country, ensuring supply of iodated salt in place of common salt, assess every 5 years the extent

of iodine deficiency disorders and impact of iodated salt, monitor the quality of iodated salt, and health education and publicity. Based on assumption that the mean intake of salt is 5 g per, say the recommended level of iodination in NGCP was one part of iodine in 25,000 to 50,000 parts of salt. WHO recommends that iodine concentration in salt should be within 20–40 ppm, to provide 150 µg of iodine per person per day (presuming that 20% iodine is lost during transport, 20% lost during cooking, and average salt consumption 10 g per person day).

## CONCLUSION

The government has been implementing a wide range of nutrition intervention programs for achieving food security at the household and individual levels. Various challenges have been identified in the review of nutritional interventions, e.g., growing demand of food production with growing population, depletion of natural resources, adverse consequences of globalization, growing concern about micronutrient deficiency, and intersectoral co-ordination mechanisms. Taking into consideration these challenges, the following strategies were recommended for 12th Five Year Plan:

- Strengthening of ICDS with special focus on pregnant and lactating mothers and children below 3 years age.
- A multisectoral program to address maternal and child nutrition in selected high burden districts.
- A nationwide information, education and communication campaign against malnutrition, coordinated by the Ministry of Women and Child Development, in consultation with the Planning Commission and Ministry of Health and Family Welfare.

In children, nutrition and growth are intricately interlinked—aberrations of one aspect tend to significantly affect the others. Therefore, appropriate nutritional policies play a pivotal role.

The changing profile in malnutrition and the expanding horizons in nutrition and child development have warranted a thorough revision and re-organization of the national nutrition policies.

## IN A NUTSHELL

1. Nutritional interventions should be targeted at the most vulnerable group i.e., children of 0–6 years, mothers and adolescent girls.
2. To reduce malnutrition social welfare programs must be implemented effectively and agencies involved in delivery of services should have strong sense of responsibility, transparency, time bound programs and accountability.
3. Changing profile of malnutrition demands that nutritional policies should be directed to felt need of population.
4. Provision of micronutrient is one of the most cost effective nutritional interventions so programs related to micronutrients should be strengthened.
5. Today's healthy children are tomorrow's healthy citizens. Future of nation lies in effective elimination of childhood malnutrition.

# Section 23 IMMUNIZATION

**Section Editors** Vipin M Vashishtha, Ajay Kalra

## Chapter 23.1

### Basic Concepts of Vaccination

Chandrakant Lahariya

Vaccine is *an inactivated or attenuated pathogen or a component of a pathogen (nucleic acid, protein) that, when administered to the host, stimulates a protective response of the cells in the immune system.* Or *an immune-biological substance designed to produce specific protection against a given disease.* The process of administering the vaccine is called vaccination. Immunization is the artificial induction of active immunity by introducing into a vulnerable host the specific antigen of a pathogenic organism. The aim of vaccination is to protect the individuals who are at risk of getting disease. The children, elderly and people with chronic diseases are the ones who are most commonly at risk. Additionally, other high risk groups such as travelers to endemic areas are at risk and should receive vaccines. Additionally, vaccination is a common strategy to eradicate, eliminate or contain disease (e.g. by mass immunization strategy) (**Table 1**). A description of relevant terms used in vaccinology is provided in **Table 2**.

### IMMUNE RESPONSE

The vaccines are different from immunoglobulin in a way that vaccine helps in developing the protective antibody in the body of individual to whom these are administered and protection is available after a lag period. However, immunoglobulins provide immediate protection. The vaccine administration is followed by two types of immune responses—primary and secondary. The primary series is the series of doses required for a primary response. There is slow development of antibody in the body after first dose of

vaccine is administered and there is period of 3–4 weeks to reach the peak antibody response (**Fig. 1**). When a subsequent dose is administered, higher and quicker immune response is received. The non-live vaccines usually require multiple doses for a satisfactory primary response. There should be a minimum of 4 weeks interval between successive doses, though larger intervals may result in higher antibody levels. The booster doses are generally given 6 or more months after the completion of primary series. The booster doses have rapid and higher antibody response, high affinity for antibody and provide longer duration of protection.

The antibody responses to vaccines are usually identified by correlates of protection. The correlates are an immune response that is responsible for and statistically interrelated with protection and are usually linked to B cell-dependent response. However, for a number of new vaccines, it is assumed that T cells also play a role in correlates of protection.

**Figure 1** Primary and booster response  
Source: Siegrist in Vaccines eds Plotkin, Orenstein & Offit.

**Table 1** Objectives of immunization strategies

Strategy	Characteristics
Control	The disease control describes the activities aimed at reducing the incidence of diseases, the duration of disease, the effect of infection and consequently the risk of transmission and the financial burden on the community. This could be done up to a locally acceptable level as a result of deliberate efforts; continued intervention measures are required to maintain the reduction. <i>Example:</i> Diarrheal diseases.
Elimination of disease	Reduction to zero of the incidence of a specified disease in a defined geographical area as a result of deliberate efforts. Continued intervention measures are required. <i>Example:</i> Neonatal tetanus.
Elimination of infections	Reduction to zero of the incidence of infection caused by a specific agent in a defined geographical area as a result of deliberate efforts, however, measures are continued to prevent re-establishment of transmission are required. The term elimination is sometimes used for describing eradication from a geographical area. <i>Example:</i> Measles, poliomyelitis.
Eradication	Termination of all transmissions of infection by extermination of infectious agent through surveillance and containment. <i>Example:</i> Smallpox.
Containment	Regional eradication of a communicable disease.
Extinction	The specific infectious agent no longer exists in nature or in the laboratory. <i>Example:</i> None.

**Table 2** Key concepts in vaccinology

Term	Definition
Antigen	A substance (protein, polysaccharide, glycolipid, tissue transplant, etc.) that is capable of inducing specific immune response. Introduction of antigen may be by the invasion of infectious organisms, immunization, inhalation, ingestion, etc.
Antibody	Protein molecule produced in response to exposure to a foreign or extraneous substance (e.g. Invading microorganism responsible for infection) or active immunization. May also be present as a result of passive transfer from mother to infant, via immunoglobulin, etc.
Immunoglobulin	Immunoglobulins are glycoprotein molecules that are produced by plasma cells in response to an immunogen and which function as antibodies. The immunoglobulins derive their name from the finding that they migrate with globular proteins, when antibody-containing serum is placed in an electrical field.
Anti-sera	It is blood serum containing polyclonal antibodies. It is used to pass on passive immunity against many diseases such as tetanus, diphtheria, botulism.
Active immunity	It is the immunity which an individual develops as a result of infection or by specific immunization and is usually associated with presence of antibodies or cells having a specific action on the microorganisms concerned with a particular infectious disease or on its toxin.
Passive immunity	Immunity conferred by an antibody produced in another host and acquired naturally by an infant from its mother or artificially by administration of an antibody containing preparation (antiserum or immunoglobulin).
Innate or natural immunity	Immunity to disease that occurs as part of an individual's natural biologic make up. It is present at birth and cannot be acquired.
Adaptive or acquired immunity	It is acquired by the body through contact with pathogens. It is specific in nature and has B-cells, T-cells, antibodies and secondary lymphoid organs as its components.
Humoral immunity or B-cell mediated immunity	It is immunity provided by the B-cells (bone marrow-derived lymphocytes), which proliferate and manufacture specific antibodies after antigen presentation by macrophages. The antibodies thus produced are of five types, viz. IgG, IgM, IgA, IgD and IgE.
Cellular immunity or T-cell mediated immunity	It is mediated via T-cells which are responsible for recognition of antigen. On contact with antigen, the T-cells initiate a chain of responses, e.g., activation of macrophages, release of cytotoxic factors, mononuclear inflammatory reactions, delayed hypersensitivity reactions, secretion of immunological mediators, etc.
Primary immune response	Following the first exposure to a foreign antigen, a lag phase occurs in which no antibody is produced, but activated B cells are differentiating into plasma cells. The lag phase can be as short as 2–3 days, but often is longer, sometimes as long as weeks or months. The amount of antibody produced is usually relatively low. Over time, antibody level declines to the point where it may be undetectable. The first antibody produced is mainly IgM (although small amounts of IgG are usually also produced).
Secondary or booster immune response	If a second dose of the same antigen is given days or even years later, an accelerated secondary or anamnestic immune response occurs. This lag phase is usually very short (e.g., 3 or 4 days) due to the presence of memory cells. The amount of antibody produced rises to a high level. Antibody level tends to remain high for longer duration. The main type of antibody produced is IgG (although small amounts of IgM are sometimes produced).
Seroconversion	It means greater than or equal to fourfold rise in antibody titer from prevaccination to postvaccination level or detectable postvaccination titer in a vaccine, who had no detectable antibody before vaccination.
Seroprotection	It is the state of protection from disease, due to the presence of humoral immunity or antibody detectable in plasma or serum. It is usually used in the context of the levels of antibody required for protection.
Protective level of immunity or correlates of protection	A specific response to a vaccine that is associated with protection against infection, disease, or other defined endpoint
Potency	Potency is the specific ability or capacity of the vaccine as measured by a laboratory test. Quantitative measure of specific ability of a product to achieve a defined biologic effect.
Immunogenicity	The ability of an antigen to induce antibodies. Alternatively, it is also defined that the capacity of vaccines to produce cell-mediated and/or antibodies-mediated immunity and/or immunological memory.

## TYPE OF VACCINES

There are a number of different types of vaccines (**Table 3**). There are differences in the route, timings, and doses of these vaccines. Another approach of grouping, the vaccines is by polysaccharide and conjugate vaccines, which have a few different characteristics, as detailed in **Table 4**.

## SURVEILLANCE FOR VACCINE PREVENTABLE DISEASES

Surveillance was first defined by Alexander Langmuir in 1963 as “the systematic collection, consolidation, analysis and

dissemination of data on specific disease”. In the recent years, surveillance constitutes a critical part of public health practice. The surveillance system is used for detecting outbreaks, assess disease burden and define disease epidemiology. It is also used for monitoring progress towards disease eradication, elimination and control, to identify circulating strains by serotypes and genotypes and to monitor vaccine performance in terms of efficacy, effectiveness against various strains and disease severity. The surveillance data is necessary to guide public health planning, developing, implementing, and decision making. It is crucial not only to improve the quality and effectiveness of collection, analysis, interpretation and display of data, but also to listen to persons who

**Table 3** Types of vaccines, their characteristics, advantages and disadvantages

Type	Characteristics	Advantage and disadvantages	Examples
Live-attenuated vaccines	These live vaccines are produced from live and attenuated organisms. The organisms are serially cultured till they lose infectivity but retain immunogenicity. These cause infection which very closely resembles natural stimulus to immune system. These can stimulate generation of memory cellular as well as humoral immune responses. Since these can multiply in the host, fewer quantities must be injected to induce protection. A single administration of vaccine often has a high efficacy in producing long-lived immunity. Multiple booster doses are not required. Also provides herd immunity.	May very rarely revert to its virulent form and cause disease (cVDPV). Live vaccines cannot be given safely to immunosuppressed individuals.  Administration of live-attenuated vaccines to people with impaired immune function can cause serious illness.  Fragile and gets easily destroyed by heat and light, proper storage is critical.	<i>Viral:</i> Polio (Sabin), measles, rubella, vaccinia, varicella zoster, yellow fever, rotavirus, influenza (intranasal) <i>Bacterial:</i> <i>Mycobacterium</i> (BCG), oral typhoid
Killed	These are preparations of the normal (wild type) infectious, pathogenic microorganisms that have been rendered nonpathogenic, usually by treatment with using heat, formaldehyde or gamma irradiation so that they cannot replicate at all. Less interference from circulating antibodies than live vaccines. Immune response is mostly humoral. Antibody titer diminishes with time.	<i>Advantages:</i> Safe to use for immunocompromised and pregnant individuals. Cheaper than live vaccines. <i>Disadvantages:</i> Since the microorganisms cannot multiply, a larger quantity and multiple doses may be required to stimulate immunity. Periodic boosters must be given to maintain immunity. Only humoral immunity can be induced. Most killed vaccines have to be injected.	Polio (Salk); Pertussis; Plague vaccine; Influenza vaccine; Typhoid vaccines
Toxoid	A <i>toxoid</i> is a bacterial toxin (usually an exotoxin) whose toxicity has been inactivated or suppressed either by chemical (formalin) or heat treatment, while immunogenicity retained.		Tetanus, diphtheria
Recombinant	The vaccines are produced using recombinant DNA technology or genetic engineering. Recombinant vaccines are those in which genes for desired antigens of a microbe are inserted into a vector.		Hepatitis B vaccine and HPV vaccines

Abbreviations: BCG, bacillus Calmette-Guérin; cVDPV, circulating vaccine-derived poliovirus; DNA, deoxyribonucleic acid; HPV, human papillomavirus.

**Table 4** Difference between polysaccharide and conjugate vaccines

Characteristics	Polysaccharide vaccine	Conjugate vaccine
Structure	Unique type of inactivated subunit vaccine composed of long chains of sugar molecules that make up the surface capsule of certain bacteria	Developed by attaching a polysaccharide antigen to a carrier protein, which helps the body recognize the antigen as a foreign substance that must be destroyed
Type of antigen	Thymic independent (Ti)	Thymic dependent (Td)
Mechanism of generating immunity	Stimulation of humoral immunity to mount immune response against the disease	Stimulation of both humoral and cell-mediated immunity for augmented immune response
Cell lines stimulated	B-cells	B-cells and T-cells, both
Immunogenicity	Low as compared to conjugate vaccines. The antibody induced is of less functionality as predominantly IgM is produced and very little IgG	High as compared to pure polysaccharide vaccines. IgG capsular antibodies and memory B-cells are also produced
Duration of protection	Shorter as compared to conjugate vaccines	Longer and consistent
Impact on carriage of bacteria	Little or only short-lived impact	Can cause reduction in carriage of bacteria
Age limitation	Not consistently immunogenic in children less than 2 years of age. Good response in adults	Can mount protective immune response in infants
Booster response	No booster response	More likely to maintain consistent immune response after repeated doses
Examples	Pneumococcal, meningococcal (groups A, C, W135, Y), <i>Salmonella typhi</i> (Vi)	Hib, pneumococcal, meningococcal

Abbreviations: Hib, *Haemophilus influenzae* type b; Ig, immunoglobulin.

are empowered to set policy in order to understand and stimulate policymakers' interests and actions. The design of a surveillance system depends upon disease characteristics and control goals:

- *Polio eradication*: Highly sensitive *case-based AFP and lab surveillance*
- *Measles control*: *Outbreak surveillance* with lab confirmation
- *Measles elimination* highly sensitive *case-based surveillance*
- Pertussis, diphtheria, invasive *Haemophilus influenzae* type b (Hib), pneumococcal and meningococcal disease, rotavirus diarrhea: *Sentinel site surveillance* for clinical syndrome plus lab confirmation
- *Hepatitis B, neonatal tetanus*: Sero-prevalence and special *population-based surveys*.

All countries use combination of surveillance systems depending upon the need and feasibility. The commonly used surveillance strategies are summarized in **Table 5**. Additionally, in India, sentinel hospital surveillance system is used for bacterial meningitis for (Hib, pneumococcal and meningococcal meningitis) and is currently being done at 11 sites in six states. Indian Rotavirus Strain Surveillance Network (IRSSN) has been functioning through four laboratories in seven regions and 10 hospitals of India. The South Asian Pneumococcal Alliance (SAPNA) and Invasive Bacterial Surveillance were conducted between 1993 and 2006 at six sites in India. The acute encephalitis syndrome surveillance was also done in India in 2006–09 at four geographical sites in the country. The Central Bureau of Health Intelligence (CBHI) at union level and State Bureaus of Health Information in the states regularly collect surveillance data on various vaccine preventable diseases (VPDs) in India. The Integrated Disease Surveillance Project (IDSP) also provides information on a few VPDs. The Indian

Council of Medical Research and National Vector Borne Disease Control Programme are also involved in the surveillance of a few VPDs in India. The Government of India and WHO collaboration of National Polio Surveillance Project (NPSP) through a wide network collect information on Acute Flaccid Paralysis for Polio eradication efforts. Lately the NPSP has also assisted in setting up outbreak-based measles surveillance system in India. These are only a few examples. The steps suggested for VPDs in any public health program are summarized in **Box 1**.

#### BOX 1 Steps in vaccine preventable disease surveillance

1. *Collect data*: The data could be collected by various types of surveillance systems (see **Table 5**).
2. *Compile data*: The units collecting data send it or compilation to an identified facility in the chain.
3. *Analyze and interpret the data*: At one place, to avoid duplication of efforts, data received is analyzed and interpreted at regular intervals. This analysis, amongst other areas, is for surveillance quality by completeness of reporting, timeliness of reporting and description by time, place and person (when, where and who gets the disease?).
4. *Take action*: The analysis and interpretation of data should be used for actions to correct any problems identified and to prevent avoidable morbidity and mortality. The appropriate authorities need to be informed. For example, if you find that there are: more cases than you expect—conduct an outbreak investigation and response; if the cases occurring in vaccinated children—this could be due to over-reporting, vaccination given at the wrong age; incorrect technique of administration or dosage and breaks in the cold chain, etc.
5. *Provide feedback*: Feedback to the reporting sites intends to comment about reporting quality, offering information to help them in solving problems and is essential to keep the staff motivated.

**Table 5** Types of disease surveillance

Type	Characteristics
Active surveillance	A system employing staff members to regularly contact health-care providers or the population to seek information about health conditions. Active surveillance provides the most accurate and timely information, but also expensive.
Passive surveillance	A system by which a health jurisdiction receives reports submitted from hospitals, clinics, public health units, or other sources. Passive surveillance is a relatively inexpensive strategy to cover large areas. Data quality and timeliness are difficult to control in such surveillance design. The reports are awaited and no attempts are made to seek reports actively from the participant in the system.
Sentinel surveillance	In a sentinel surveillance system, a prearranged sample of reporting sources agrees to report all cases of defined conditions, which might indicate trends in the entire target population. When properly implemented, these systems offer an effective method of using limited resources and enable prompt and flexible monitoring and investigation of suspected public health problems. Examples of sentinel surveillance are networks of private practitioners reporting cases of influenza or a laboratory-based sentinel system reporting cases of certain bacterial infections among children. Sentinel surveillance is excellent for detecting large public health problems, but it may be insensitive to rare events.
Periodic population-based surveys	Population-based surveys can be used for surveillance, if they are repeated on a regular basis. Examples of population-based surveys in surveillance include the HIV-prevalence surveys, household surveys, and the demographic and health surveys that many developing countries conduct every five years. Population-based surveys require careful attention to the methodology, particularly, the use of standard protocols, supervision of interviewers, comparable sampling strategy, and standard questionnaires.
Integrated surveillance	A combination of active and passive systems using a single infrastructure that gathers information about multiple diseases or behaviors of interest to several intervention programs.
Syndromic surveillance	An active or passive system that uses case definitions that are based entirely on clinical features, without any clinical or laboratory diagnosis (for example, collecting the number of cases of diarrhea rather than cases of cholera, or <i>rash illness</i> rather than measles). Because syndromic surveillance is inexpensive and is faster than systems that require laboratory confirmation, it is often the first kind of surveillance begun in a developing country.
Behavioral risk factor surveillance system (BRFSS)	An active system of repeated surveys that measure behaviors that are known to cause disease or injury (for example, tobacco or alcohol use, unprotected sex, or lack of physical exercise). Because the aim of many intervention program strategies is to prevent disease by preventing unhealthy behavior, these surveys provide a direct measure of their effect in the population, often long before the anticipated health effects are expected.

## VACCINE EPIDEMIOLOGY

Vaccine epidemiology is the study of the impact of vaccines and treatment on infectious diseases to understand better the response to these interventions at the individual and population levels in order to improve their effectiveness.

### Basic Reproductive Number ( $R_0$ )

One of the key determinant of incidence and prevalence of infection is the basic reproductive number or  $R_0$ , which measures the average number of secondary cases generated by one primary case in a susceptible population. A number of factors determine its magnitude, including the course of infection in the patient and the factors that determine transmission between people. The magnitude of  $R_0$  varies according to location and population—it is strongly influenced by birth rate, population density and behavioral factors. The magnitude of  $R_0$  can be ascertained by cross-sectional and longitudinal serological surveys. Another related term is effective reproduction number or  $R_t$ , which is infections caused by each new case occurring at time,  $t$ . For organism to survive:

- $R_0 = 1$  (Case must attempt to infect at least one person)
- $R_0 > 1$  (Expansion of infected individuals)
- $R_0 < 1$  (Shrinking pool of infected individuals)

To calculate the magnitude of  $R_0$ , a few key epidemiological, demographic and vaccination program-related parameters should be known. The parameters such as average age at the infection prior to mass vaccination,  $A$ ; life expectancy of the study population,  $L$ ; and the average duration of protection by maternal antibody,  $M$  are considered. While the life expectancy and average age of protection by maternal antibody are known, the average age of infection prior to mass vaccination has been studied in select populations and provided in **Table 6**. This information in the following formula could be used for deriving the magnitude of  $R_0$ :

$$R_0 \equiv (L - A)/(A - M)$$

There are a number of studies conducted in different parts of the World to assess the average age of infections  $A$ , and to derive basic reproductive number. The findings are summarized in **Table 6**. The study of epidemiological principles provides an opportunity for deriving some useful and applicable information for disease control. For example, it is possible to estimate the fraction of each birth cohort that must be immunized to block transmission of a given disease,  $p_c$  can be calculated by the following formula:

$$p_c \equiv [L - A]/(L - b)/\varepsilon$$

Where, the parameter  $b$  is the average age at first vaccination,  $L$  is life expectancy (related to the net birth rate), and  $A$  is the average age at infection prior to mass immunization. Vaccine efficacy  $= \varepsilon$ , ranging from 0 to 1. The magnitude of  $p_c$  — the fraction of the susceptible population that must be immunized to block transmission of a disease could be derived with the use of  $R_0$ , as follows:

$$p_c = [1 - 1/R_0]/\varepsilon$$

This concept of  $R_0$  is useful at multiple levels. For example, it provides assessment of the critical fraction of each population immunized, if eradication is targeted ( $p_c$ ). For a vaccine which is considered reasonably protective, the eradication criteria or threshold would be:

$$p_c > \frac{[1 - 1/R_0][1 + L/V]}{\varepsilon}$$

Where,  $p_c$  is the critical fraction of each cohort immunized,  $R_0$  is the basic reproductive number,  $L$  is life expectancy,  $V$  is the duration of vaccine protection and  $\varepsilon$  is vaccine efficacy. (More on vaccine efficacy in subsequent paragraphs.) The eradication threshold for imperfect vaccines (the vaccinated individuals acquire infection but progression to disease is slower) would be:

$$p_c > \frac{[1 - 1/R_0][1 + L/V]}{\varepsilon [1 - R_{ov}/R_0]}$$

Where  $p_c$  is the critical fraction of each cohort immunized,  $R_0$  is the basic reproductive number for unvaccinated,  $R_{ov}$  is the reproductive numbers for vaccinated,  $L$  is life expectancy,  $V$  is the duration of vaccine protection and  $\varepsilon$  is vaccine efficacy. This epidemiological concept explains that eradication is difficult when  $R_0$  large and population density plus net birth rate high.

### Force of Infection

The force or rate of infection is the risk of being infected. The force of infection depends upon prevalence of infectious individuals, rate of contact between individuals, and infectiousness of individuals, etc. As transmission is a dynamic process, force of transmission can change over period of time. The force of infection could be estimated by the following formula:  $\lambda(a) = p(a)/[L(1 - e(-a/L))]$ ; where, force or rate of infection  $\lambda$  and the average age of infection  $A$ , the proportion seropositive at age  $a$  is  $p(a)$ , average force or rate of infection  $\lambda$  over the interval 0 to  $a$  years of age and  $L$  is life expectancy. The relation of this with other concepts is as follows:

$$A \approx 1/\lambda; R_0 \approx L/A; \text{ and } p_c = (1 - 1/R_0) = (1 - A/L)$$

**Table 6** Average age of infection and basic reproductive number of select diseases

Infection	Average age at infection, A	Location/time period	
Measles virus	5–6 years 2–3 years	USA 1955–58 Bangkok, Thailand 1967	
Rubella virus	9–10 years	Sweden 1965	
Varicella virus	6–8 years	USA 1921–28	
Polio virus	12–17 years	USA 1920–60	
Mumps virus	7–8 years	England & Wales 1975	
Smallpox virus	10–15 years	Bangladesh 1940	
Infection	Location	Time period	$R_0$
Measles	England Canada	1947–50 1912–13	13–15 11–13
Varicella	USA	1943	7–8
Mumps	Netherlands	1970–80	11–14
Rubella	West Germany	1970–79	6–7
Polio	USA	1955	5–6
Influenza A (H1N1)	England	2010	1–1.5

## Vaccine Efficacy and Effectiveness

The vaccines have effect at both individual and population levels. The *biological or individual level effect* of vaccines includes effects on susceptibility (VEs), on infectiousness (VEi) and on the disease progression (VEp). The *population level effects* of vaccination depend on the coverage and distribution of the vaccines, as well as on how well different groups mix with each other. These effects could result from biologic effect as well as behavioral effects of the vaccination. Overall, public health effect of vaccination program depends on the effect in both vaccination and the unvaccinated population. This gives at least three types of population level effects of vaccination:

1. *Indirect effect*: The population level effect of widespread vaccination on people not receiving vaccine.
2. *Total effect*: Combination of population level effect and effect of vaccination on individuals receiving vaccine.
3. *Overall public health effect*: The effect of vaccination program based upon weighted average of indirect effect on the individual not receiving vaccine and total effect on individual receiving vaccination.

In this context, the terms vaccine efficacy, vaccine effectiveness and program effectiveness are commonly used.

### Vaccine Efficacy

*Vaccine efficacy* is the percentage reduction in disease incidence attributable to vaccination [usually] calculated by means of the following equation:

$$VE (\%) = (RU - RV) / RU \times 100$$

Where RU = The incidence risk or attack rate in unvaccinated people and RV = The incidence or attack rate in vaccinated people. The equation for vaccine efficacy can be reformulated as:

$$VE = 1 - RV / RU \times 100$$

Where RV/RU is the relative risk or rate ratio in vaccinated and unvaccinated. The vaccine efficacy is measured by observational studies under field conditions within a vaccination program or measured by trials conducted under normal program conditions. The vaccine efficacy for a number of vaccines is known, i.e., measles vaccine 90–95%; mumps: 72–88% and rubella 95–98%. In the vaccine trials, the vaccine efficacy is amongst other things (including safety) are assessed and this is an important criterion for licensing of the vaccines and for decision on programmatic use. Vaccine efficacy is dependent upon internal or individual factors for example, efficacy of measles vaccination depends on the presence of inhibitory maternal antibodies, the immunologic maturity of the vaccine recipient and the dose and strain of vaccine virus.

### Vaccine Effectiveness

*Vaccine effectiveness* is the reduction in the clinical events that might be expected to be associated with the disease but could also to be caused by other agents. Under programmatic conditions, effectiveness of measles vaccine depends upon: the coverage, cold chain maintenance, correct injection techniques and safety, inaccurate record-keeping/recall resulting in misclassification errors, and population-specific factors (HIV infection, malnutrition, etc.). The most commonly deployed study design to assess a vaccine's effectiveness is retrospective case control analysis and the odds ratio thus obtained can be used to calculate vaccine effectiveness as:

$$\text{Effectiveness} = (1 - OR) \times 100$$

The vaccine effectiveness could be assessed by observational studies—cohort studies, household contact study, case-control study and screening. How the information from screening could be used for arriving of vaccine effectiveness is shown in **Figure 2**. The

**Figure 2** Relationship between percentage of cases vaccinated and vaccine efficacy

vaccine efficacy and effectiveness have been used interchangeably in scientific literature. The vaccine effectiveness is often referred as vaccine efficacy in the field conditions. In simple terms, vaccine effectiveness is a combination of vaccine efficacy and field conditions such as coverage, immune status of population, conditions under which vaccine administered (cold chain), etc. In general, efficacy is always higher than effectiveness. However, vaccines which show herd effect could have higher effectiveness than vaccine efficacy. For example, under programmatic conditions vaccine effectiveness is lower than vaccine efficacy while herd effect improves effectiveness and can take it above efficacy. If analyzed from an outbreak, the formula for estimation of *vaccine effectiveness* is *attack rate among vaccinated versus attack rate among nonvaccinated*.

### Program Effectiveness

The *program effectiveness* refers to the assessment of effectiveness of individual antigens in districts, states and national level by various epidemiological techniques. The program effectiveness is also assessed by looking at the trends in the occurrence of VPDs (**Fig. 3**) in identified settings and situation, before and after vaccine introductions. Overall mortality reduction is often considered as an indicator of vaccine program effectiveness/impact. Program effectiveness is combination of more than one vaccine's effectiveness. The impact is the population level effect of vaccination program, which depends upon many factors including vaccine efficacy, herd immunity and effectiveness. The serological and epidemiological studies can be used to determine the vaccine efficacy and program effectiveness. Amongst serological studies, two broad types such studies utilized for vaccine efficacy. The *seroconversion studies*, which are useful to measure the induction of an immune response in the host and, in absence of disease, indicate persistence of antibody and immunity. These studies are particularly useful in choosing the appropriate age for vaccination. *Seroprevalence studies* monitor the prevalence of antibodies due to disease in the population and indicate the pattern of occurrence of disease.

The screening of the population is another approach which has been used frequently for assessing the vaccine efficacy. This method provides an estimate of vaccine efficacy, if some other information is available. The formula used for assessing vaccine efficacy is given here and **Figure 2** is used for assessing vaccine efficacy:

$$PCV = [PPV - (PPV * VE)] / [1 - (PPV * VE)]$$

Whereas PCV = Proportion of cases occurring amongst vaccinated individuals; PPV = Proportion of population vaccinated;

**Figure 3** Reported vaccine preventable disease cases in India; 1980–2010

Source: Central Bureau of Health Intelligence (CBHI), India.

and VE = Vaccine efficacy. If any of the two values in this formula is known, then third value can be derived.

### Vaccine Failure

When a person who has been fully vaccinated develops the disease against which they have been vaccinated, it is referred to as vaccine failure. This could be of two types:

1. *Primary vaccine failure* occurs when the recipient does not produce enough antibodies when first vaccinated. Infection can therefore occur at any time post vaccination. This can occur in about 10% of those who receive the measles-mumps-rubella (MMR) vaccine.
2. *Secondary vaccine failure* occurs when an adequate number of antibodies are produced immediately after the vaccination, but the levels fall over time. The incidence of secondary vaccine failure therefore increases with time after initial vaccination and booster doses are required. This is a feature of many of the inactivated vaccines.

### HERD IMMUNITY

*Herd immunity* may be defined as the resistance of a group or a community in total, against the invasion and spread of an infectious agent as a result of a large proportion of individuals in the group being immunized. The herd immunity or contact immunity develops in case of certain live vaccines (e.g. OPV) wherein the nonvaccinated individuals also develop immunity to the pathogen just by coming in contact with the vaccinated individual. The level of herd immunity can be assessed through cross-sectional and longitudinal serological surveys. Additionally, the level of herd immunity can be measured by reference to the magnitude of reduction in the value of  $R_0$ . Herd immunity threshold ( $H$ ) is defined as the minimum proportion to be immunized in a population for elimination of infection.

$$H = 1 - 1/R_0 = (R_0 - 1)/R_0$$

As the immunization coverage increases, the incidence and prevalence rate may decrease not only due to the direct effect of immunization *per se* but also because of herd effect.

### HERD EFFECT

Herd effect or herd protection is *the reduction of infection or disease in the unimmunized segment as a result of immunizing a proportion of the population* or is *the change induced in epidemiology (incidence reduction) among unvaccinated members when a good proportion is vaccinated*. Herd effect is seen only for infections where humans are the source, and it extends beyond the age, a vaccine is given. Hib vaccine given to infants indirectly also offers protection to other under five children, and also adult of other family members.

### EPIDEMIOLOGIC SHIFT

Epidemiological shift or transition denotes the change in the pattern of disease in a specified population. The impact on person characteristics of disease is, shift in the age, observed consistently in communities with partial immunization coverage. The phenomenon is termed as epidemiological shift and diseases of importance are hepatitis A, rubella and varicella, wherein the severity of disease worsens with advancing age. Vaccination artificially alters natural selection leading to extinction of some genotypic families and sustained propagation of others at the expense of the genotype against which the vaccine efficacy is higher; e.g., Type 2 polio virus got eradicated way back in 1999 mainly due to better vaccine efficacy of tOPV against it while Type 1 and 3 continue to circulate even till today.

One of the well-documented examples of epidemiological shift is the introduction of MMR vaccine in Public Health Vaccination program in Greece with inconsistent coverage. The MMR vaccine was introduced in Greece in 1975. The immunization coverage ~50–60% among boys and girls aged 1 year. This way, a large proportion of women susceptible kept on increasing. In 1993, it was noted that

Greece had highest incidence of congenital rubella syndrome (CRS). The reason was with low MMR coverage, the shifting epidemiology and susceptible population. The epidemiological shift can cause more harm than good. This highlights the need and importance for high coverage at the time introduction. This is sometimes referred as *perverse outcome*, where disease severity increases with age at infection, vaccination can increase the burden of disease, by raising average age of infections (the total number of infections fall but the total number of severe disease increases, i.e., CRS, measles encephalitis, orchitis due to mumps, etc).

## INTRODUCTION OF NEW VACCINES

Usually, the countries have their own criteria for decision making on introducing a new vaccine in national immunization programs. The usual criteria are disease burden, availability of safe and effective vaccine, cost effectiveness and program sustainability. The usual questions, which are deliberated before making decisions on the introduction of new vaccines for any target group or National Immunization Program includes:

1. Is the disease under consideration a public health problem?
2. Is the immunization the best control strategy for this disease?
3. Is the existing immunization program working well enough to add a new vaccine?
4. What will be the net impact of the vaccine?
5. Is vaccine a good investment and what are the alternatives?
6. How will the vaccine be funded and how the program would be sustained once external funding is over?
7. How will the addition of the new vaccine be implemented?

The vaccine epidemiology provides or helps to provide answers to these questions. These answers are supported by information on disease surveillance, modeling, vaccine efficacy and program effectiveness.

## DESIGNING IMMUNIZATION SCHEDULE

The immunization schedule aims to strike a balance between immunological and epidemiological determinants. It aims for achieving protective immune response prior to the age when children are most vulnerable. It also aims for balance between inducing reasonable protection prior to vulnerable age versus inducing optimal immune response. Starting late might induce a higher response, but miss the vulnerable age, wider intervals between doses gives a better response, but delays induction of immunity, leaving children vulnerable in a crucial period in their life. The disease epidemiology varies in different populations, therefore, a schedule that is used in one population is not the best for another; need to individualize and tailor to suit local needs. The determinants of optimal immunization schedule can be organized in four broad categories:

1. *Immunological*: Minimum age at which vaccine elicit an immune response; number of doses required; interval between doses, if multiple doses are required
2. *Epidemiological*: Susceptibility for infection and disease; disease severity and mortality.
3. *Programmatic*: Opportunity to deliver with other scheduled interventions; increase coverage by limiting the required contacts.
4. *Safety of the vaccines*.

The decisions on opting for a particular immunization schedule are affected by a number of epidemiological determinants as summarized here and also described below:

**Vaccine and antigen type** The immunization schedule is affected by the types of vaccines, i.e., live versus non-live vaccines. There is higher intensity innate response with live vaccines. With higher antigen content following replication and prolonged antigen persistence with live vaccines. Similarly, use of adjuvants enhances response to non-live vaccines. It is also dependent upon antigen type as polysaccharide antigens are T-cell independent and have

lower antibody response of shorter duration and no booster response. The protein antigens or antigens conjugated with some proteins have a higher immune response and booster effect (**Table 3**).

**Number of doses** The number of doses required varies by vaccines. In general, live vaccines induce immunity with a single dose and inactivated vaccines require multiple doses. Some live vaccines only induce immunity in a relatively small proportion of vaccines, requiring multiple doses to induce immunity in an optimal proportion of population, e.g., OPV. Number of doses required may also vary by age. More doses of conjugate vaccines are required in young infants. Duration of immunity also influences the requirement for additional doses, either to boost or to re-induce immunity (for T-cell independent antigens). The non-live vaccines generally require booster doses for long-term immunity. Since vaccines seldom produce sustained mucosal immunity, natural boosting from mucosal infection occurs frequently.

**Age and route of administration** The age reflects the maturity of the immune system. For example, children younger than 2 years are usually do not respond to polysaccharide antigens. Greater numbers of doses are required for primary response (PS-conjugate vaccines). At younger age, there is inhibitory effect of maternal antibodies and that is why measles vaccine is administered at 9 months of age.

**Route of administration** The route of administration is less of an issue with live vaccines. However, most non-live vaccines have to be given intramuscular (IM) or intradermal (ID) because of presence of adequate number of antigen presenting cells (APCs) in these areas. Mucosal immunization with non-live vaccines is difficult with the only exception of oral cholera vaccine (killed  $\pm$  B subunit). The core principle is that organisms should be able to replicate at site of administration. Following replication, organisms disseminate and induce generalized immune response.

**Programmatic considerations in scheduling vaccination** The efforts are made to match the optimal schedules (based on immunological and epidemiological considerations) with programmatic realities in the local population to achieve maximum effect on disease control. The predominant modality of vaccine delivery, e.g., fixed sites or outreach, need to be considered, including the number of contacts required with health systems, exploring options of linking with delivery of other interventions and explore delivery mechanisms that increase coverage and reach the *hard to reach*, e.g., campaigns, immunization days, etc.

## ASSESSMENT AND EVALUATION OF THE IMMUNIZATION PROGRAM

It is imperative to ensure the quality of immunization services, is evaluated and assessed on the regular basis. The epidemiological methods provide useful tools for such evaluations.

**Thirty-cluster survey** This is a standard WHO methodology to determine immunization coverage based on a survey of small number of individuals (e.g., 210 in 30 clusters of 7 children each). The home visits are made and immunization record or history is taken for children aged 12–23 months. The survey provides fairly correct information about immunization coverage in the area. However, it is important that these clusters are selected based upon standardized methodology and statistical tools.

**Seventy-five household survey** In this approach, 75 households near the health facility are surveyed. This methodology follows the notion that if the households closest to the facilities could provide the best estimates of immunization coverage.

Missed opportunity survey, Lot Quality Assurance Survey (LQAS), Multi-indicator Cluster Survey (MICS) and Coverage Evaluation Surveys (CES) are the other methods.

### IN A NUTSHELL

1. Vaccines are the proven cost-effective interventions to reduce mortality and morbidity (in all age groups). There are licensed vaccines against nearly 27 pathogens and nearly 130 are under research and stage of clinical trials.
2. Vaccines have successfully controlled scourge caused by pathogens such as smallpox (eradicated) and poliomyelitis (nearly eradicated).
3. Vaccinology combines the principles of microbiology, immunology, public health, epidemiology and pharmacy, amongst other.
4. The knowledge of principles of vaccine epidemiology, i.e., basic reproductive number, vaccine efficacy and effectiveness, herd immunity, epidemiological shift and disease surveillance need to be widely understood by all practitioners who administer vaccines.

## Chapter 23.2

# Vaccine Administration Practices

Satish V Pandya

Selecting proper route and site of vaccine administration and ensuring optimum delivery with right technique are of paramount importance. Health-care providers need to take measures to prevent transmission of infection during the process of administration. Steps taken to ensure comfort and pain alleviation for the vaccines go a long way in sustaining faith in the vaccination programs. This also requires adequate training of paramedical staff and good communication skills for the health-care providers. With large number of vaccines to be administered proper documentation is very important to prevent errors in schedule, duplication of doses and missing of doses of vaccination.

### ROUTES AND TECHNIQUES OF VACCINE ADMINISTRATION

Various routes are recommended for administration of vaccines. These include intramuscular, subcutaneous, intradermal, oral, and nasal. Route of vaccine administration varies with individual vaccine. The route depends upon the immunogenicity and composition of vaccine. It is determined during pre-licensure studies. One vaccine may have option of more than one route. The route of administration used should be as mentioned by the manufacturers and guidelines published by professional organizations such as Advisory Committee for Vaccination and Immunization Practices by Indian Academy of Pediatrics (ACVIP-IAP). The site of administration is also determined so as to give optimum immune response and minimize injury to surrounding tissues. Deviation from labeled route and site can result in adverse effects and less than desired immune response. For example, if hepatitis B vaccine is given in gluteal region the immunogenicity is lowered.

Most parenteral vaccines are given by either intramuscular or subcutaneous route (as an exception *Bacillus Calmette-Guérin* (BCG) and sometimes rabies vaccine are given intradermally). Subcutaneous route is used for measles, measles-mumps-rubella (MMR), varicella, meningococcal polysaccharide, Japanese encephalitis and yellow fever vaccines. Either subcutaneous or intramuscular routes can be used for pneumococcal polysaccharide vaccine and inactivated polio vaccine (IPV). Rest of the vaccines are to be given intramuscularly. If vaccines recommended to be given by subcutaneous route are given intramuscularly, then no harm is done. However, those designated to be given intramuscularly should not be given subcutaneously as this will cause more local side effects and may have reduced immunogenicity.

### Intramuscular Injections

This route is generally recommended for adjuvant-containing vaccines. Vaccines containing adjuvant (e.g., aluminum adsorbed DTaP, DTwP, DT, hepatitis B, hepatitis A) must be injected deep intramuscularly. Such vaccines when given by other routes such as subcutaneous or intradermal can cause significant local inflammatory reactions and result in pain, induration, skin discoloration and granuloma formation.

Site of intramuscular injection depends upon the volume of vaccine to be administered, size of the muscle mass and thickness of overlying subcutaneous tissue. The quadriceps

muscle mass in anterolateral aspect of thigh is recommended for infants less than 12 months of age and deltoid muscle in upper arm is recommended for older children above 12 months of age, adolescents and adults. Anterolateral aspect of thigh can also be used for older children but it may cause transient limping. When more than two vaccines are to be administered on the same limb anterolateral aspect of thigh is preferred to get a larger muscle mass. However, the injections should be separated by distance of more than one inch to differentiate local reactions. If a vaccine and an immune globulin are to be administered simultaneously (e.g., Hepatitis B vaccine and HBIG), separate anatomic site should be used for each one.

Gluteal region is not generally recommended for routine vaccination due to potential risk of injury to sciatic nerve. This site is uncommonly used when a large volume of immune globulins preparations are to be administered intramuscularly. The needle is inserted in upper outer quadrant and directed anteriorly. A 22–25 gauge needle is usually used for most intramuscular vaccines. The ideal needle length depends upon the thickness of subcutaneous tissue, desired depth below the muscle tissue in which the vaccine is to be injected and the technique used. There are two techniques used for intramuscular injections:

1. The *bunching* technique consists of gently bunching the muscle with freehand and the needle is inserted perpendicular to the skin. A 7/8–1 inch (22–25 mm) needle is recommended with this technique.
2. The second technique consists of stretching the skin flat over the injection site with thumb and index finger and inserting the needle perpendicular to the skin. A 5/8 inch (16 mm) needle is recommended with this technique.

These recommendations for infants and older children are based on studies with ultrasonography to determine the thickness of subcutaneous tissue and muscle layer over deltoid and anterolateral thigh of children. For adolescents and adults, the needle length may be determined based on the weight and sex of the vaccines. The range may be from 5/8-inch to 1.5 inch (16 mm to 38 mm). Aspiration by pulling back on the syringe plunger is not recommended as there are no large blood vessels at the routinely recommended sites. It is also more painful to infants.

After intramuscular injection, the needle should be withdrawn a few seconds after finishing the administration to prevent backflow of vaccine into the needle track. After withdrawal of needle, the site should be pressed for few seconds with a cotton swab. It should not be rubbed. In patients with bleeding disorders who require intramuscular vaccination, the administration of vaccine should be scheduled shortly after specific therapy. Firm pressure should be applied at the site for 2 minutes or more. If feasible, subcutaneous route may be preferred.

### Subcutaneous Injections

With subcutaneous injection, the risk of local neurovascular injury is reduced and is recommended for those vaccines which are less reactogenic but immunogenic when administered by this route. Live-virus vaccines such as measles, mumps and rubella are the examples. The usual sites for subcutaneous injections are thigh for infants less than 12 months of age and upper, outer triceps area for children above 12 months age. A 5/8-inch needle of 23–25 gauge is recommended. The vaccine is administered below the dermal layer of tissues. To avoid entry into the muscles, skin and subcutaneous tissue should be held and raised as a fold between thumb and finger and needle is inserted at an angle of 45°.

### Intradermal Injections

Intradermal administration is mainly recommended for BCG vaccination. It is also used for rabies vaccine when administered

on a large scale with large number of vaccines. The deltoid region of left upper arm is recommended for BCG vaccine. A 3/8–3/4 inch, 25–27 gauge needle is used. The needle is inserted into the epidermis at angle parallel to the long axis of the upper arm. The entire bevel should penetrate the skin and a bleb should be raised by injected solution. This confirms intradermal injection rather than subcutaneous injection. Inadvertent injection into subcutaneous layer may result in suboptimal immunogenic response.

Summary of recommended site, route, technique, and needle length for various ages is given in **Table 1**.

### Oral Administration

Oral polio vaccine (OPV) and rotavirus vaccines are given orally. The vaccinee should be administered slowly over in side of the cheek to prevent gag reflex. One should ensure that the vaccine is swallowed and retained. If OPV is spat out or regurgitated within 10 minutes of administration, it should be repeated immediately. However, readministration of rotavirus vaccine is not recommended if it is spat out or regurgitated. (Manufacturer's instructions should be followed). Breastfeeding before or after oral administration of vaccine is not contraindicated.

### Intranasal Route

Live-attenuated influenza vaccine (LAIV) is administered intranasally. This vaccine is not available in India at present. The administration device is a nasal sprayer with a dose divider clip that allows introduction of one 0.1 mL spray into each naris. The tip should be inserted slightly into the naris before administration. The vaccine dose need not be repeated, if the person coughs or sneezes after administration. Introduction of low levels of vaccine virus into the environment is likely and unavoidable. Severely, immunocompromised persons should not administer LAIV.

### ENSURING COMFORT AND ALLEVIATING PAIN

Several methods are used to reduce discomfort and alleviate pain associated with vaccine administration in young infants and children. Supportive and compassionate attitude of the health-care providers reduce the anxiety of parents and children. A child friendly environment with various distractions such as

colorful pictures, toys and music may help to comfort the child. Pretreatment with topical lidocaine—prilocaine emulsion cream (EMLA) or patch causes superficial anesthesia and decreases the pain associated with vaccination. It does not seem to interfere with immune response. Topical refrigerant spray can work for short periods following vaccination. Use of antipyretics before or at the time of vaccination is not evidence based. However, antipyretics can be used to treat fever and local discomfort following vaccination. Breastfeeding and oral administration of sweet fluids (sucrose) just before injection have calming effect and may serve as potential analgesics.

### STERILE INJECTION PRACTICES

The World Health Organization (WHO) defines a safe injection as one that

- Does not harm the patient
- Does not expose the health worker to avoidable risk
- Does not result in waste that puts other people at risk.

There is risk of transmission of blood-borne pathogens when injections are administered. Thorough hand washing with soap and water for 2 minutes using WHO, 6 steps is recommended before each vaccine contact to reduce the risk of microbial contamination and transmission of microbes between recipients and health-care providers. Hand cleansing with an alcohol-based antiseptic hand rub is an alternative. The use of protective gloves is not routinely recommended unless the health-care provider is likely to have contact with potentially infectious body fluids or has open lesions on the hands.

Bacterial infection at injection site and abscess formation can occur, if proper care is not taken. The skin at injection site needs to be prepared to prevent contamination with bacteria on the skin. This can be achieved with 70% isopropyl alcohol or other disinfectant. This should be allowed to dry before giving injection.

Transmission of pathogens can occur, if the needles, syringes, vaccines and other equipment used for injection are contaminated. This can be prevented by certain measures. The needles and syringes should be sterile. A separate needle and syringe should be used for each injection. Changing needles between drawing vaccine from a vial and injecting it into a recipient is not necessary.

**Table 1** Injection site, type of needle and technique

Age	Site	Type of needle	Comments
Intramuscular injections (needle should enter at 90° angle)			
Preterm and neonates	Anterolateral thigh (junction of middle and lower third)	22–25G, 5/8 inch	Skin should be stretched between thumb and forefinger
Infants (1 to < 12 months)	Anterolateral thigh	22–25G, 1 inch	Bunch the skin, subcutaneous tissue and muscle to prevent striking the bone
Toddlers and older children (12 months–10 years)	Deltoid	22–25G, 5/8 inch	Skin should be stretched between thumb and forefinger
	Or Anterolateral thigh	22–25G, 1 inch	Bunch the skin, subcutaneous tissue and muscle
Adolescents and adults (11 years onwards)	Deltoid or anterolateral thigh	< 60 kg 1 inch	
		> 60 kg 1.5 inch	
Subcutaneous injections (needle should enter at 45° to the skin)			
Infants	Thigh	22–25G, 5/8 inch	
Children >12 months	Outer triceps	22–25G, 5/8 inch	
Intradermal injections			
All ages	Left deltoid	26/27G, 0.5 inch	A 5 mm wheal should be raised

The septum of a multidose vial should be swabbed with alcohol prior to each withdrawal and needle should not be left in the vial. Single-use disposable syringes and needles should be used. To prevent needle-stick injury syringe and needle should be discarded as single unit in a puncture-proof container. Recapping of needle should not be done. Autodisable syringes help to prevent reuse of disposable syringes. Needle-shielding devices ensure protection against needle-stick injuries.

*Jet injectors* are needle-free devices that drive liquid medication through a nozzle orifice, creating a narrow stream under high pressure that can deliver the vaccine into intradermal, subcutaneous or intramuscular tissues. They prevent needle-stick injuries and overcome other problems associated with disposable syringes and needles. They are safe and effective and immune responses generated are equivalent or higher than those with needle injection. Local reactions such as redness, induration, pain and ecchymosis at the site of injection are more frequent.

Paramedical staff needs to be trained to ensure safe immunization practices. Periodic supervision is equally important.

## ERRORS OF ADMINISTRATION

Errors in medication are not uncommon. Vaccination is no exception. Programmatic errors such as giving inappropriate medication instead of vaccine can cause avoidable morbidity and mortality. Such events also put vaccination programs in disrepute and cause setback. It is absolutely necessary to take all measures to prevent such errors.

- Syringes should be filled only before administration because several vaccines look similar in appearance when filled in syringe. There should be a system of multiple checks to minimize human error and to ensure that only right vaccinee is given to the right vaccine.
- Vaccine should be inspected for expiry date. If the label has come off, the vaccine should be discarded. The vial should be shaken thoroughly to obtain a uniform suspension. Any abnormal looking vaccine or diluents should be discarded irrespective of expiry date.
- For reconstitution of lyophilized vaccines, only vaccine-specific supplied diluents should be used. The reconstitution should be done just prior to administration. Reconstituted vaccine should be discarded, if not used within the stipulated time (2–4 hours).
- Different vaccines should not be mixed in same syringe unless specifically licensed for such a use. Change of brand for a vaccine with same composition is generally not recommended but may be done in case of non-availability of the same brand or if the records are not clear about the brand used in past.
- Principles of cold-chain maintenance are discussed separately in another chapter of this section.

## DOCUMENTATION AND RECORD KEEPING

In the present era of availability of multiple vaccines, immaculate record keeping is an important aspect of good immunization practices. Availability of vaccines with several different brand names, combinations with different brand names, vaccines with different number of serotypes and patients getting vaccination at different setups often result in confusion regarding the true immunization status of the child. Deviation from recommended schedule and missed doses make the matters worse. Some of the commonly encountered problems with record keeping are illegible dates, no mention about brands, no mention about valency of vaccine, confusing signs used by individual practitioners (for example, a tick mark is done against “OPV/IPV” though only OPV has been administered) and confusion between due date and date

of administration. Such improper vaccination records result in missing of doses, duplication of doses and improper schedules.

The ideal vaccination record should have following:

- Date of vaccination
- Product administered
- Manufacturer’s name or brand name
- Lot or batch number
- Expiry date
- Site and route of administration
- Name, address and title of the health-care provider administering the vaccine.

Additionally, the record should be legible, next due date should be written away from the record of date of administration to avoid confusion, vaccination record card should be of good quality paper to prevent wear and tear and the card should show a recommended schedule of vaccination from birth to adolescence. Computerized vaccination record is recommended in office practice. This will ensure easy retrieval in case of lost or damaged record card and can instantly generate a schedule according to age and vaccines administered in past.

## PREPAREDNESS FOR LIFE-THREATENING ADVERSE EVENTS FOLLOWING VACCINATION

Ideally, the vaccinee should be observed for at least 15–20 minutes following vaccination for any allergic reactions. Each health-care facility offering vaccination program should have a functional resuscitation place. It should be equipped with working suction facility, airway, oxygen, bag and mask, intubation equipment, intravenous access and medications necessary for treating anaphylaxis (adrenalin, normal saline and hydrocortisone).

## Communicating with Parents and Children

The parents must be explained about need, efficacy, safety and cost of vaccines being offered. One-to-one discussion is required. A balanced scientific view needs to be given about the vaccines. The care providers need to be updated on newer developments in rapidly progressing field of immunization. Parents should be imparted enough knowledge about vaccine-related issues to empower them to make informed decisions regarding vaccination. The common expected side effects should be informed in advance so that parents do not become anxious. As mentioned earlier medication for treating fever and pain should be prescribed to be used, if required. Children should also be offered age appropriate information and explained about the administration process. A positive and caring attitude reassures children and makes the inevitable pain more tolerable. This will ensure continued follow-up and reduce incidence of drop out and missed doses.

### IN A NUTSHELL

1. Do not deviate from the recommended route, site and technique.
2. Children should be provided a friendly environment with caring attitude of personnel and measures should be taken to alleviate pain and discomfort.
3. Infection control and safe vaccination practices need utmost attention. Errors can be avoided, if guidelines are strictly followed.
4. Proper documentation of vaccine administered is essential.
5. The paramedical staff should be adequately trained and supervised.
6. Vaccination setup should be well prepared to manage life-threatening events like anaphylaxis.
7. Proper communication regarding need, safety, efficacy and cost is must.

## Chapter 23.3

# Scheduling of Vaccines

Vipin M Vashishtha

Vaccines are life-saving, great public health tools. More and more vaccines are now developed and used worldwide, first in developed countries and later, in poor developing countries. In developing countries, particularly, they are licensed and introduced first in a private market for individual use, and later some of them inducted into national immunization programs for mass use after a *lag period* which is considerably long for poor developing countries than for industrialized, developed nations. Whether used in individual practice or in large scale mass immunization programs, they need to be scheduled in a particular way so that not only the best possible protection is achieved, but the maximum utilization of their other inherent virtues is also ensured.

### DETERMINANTS OF OPTIMAL IMMUNIZATION SCHEDULE

To devise an optimal immunization schedule, various considerations such as appropriate immunologic response to vaccines, epidemiology and burden of vaccine-preventable diseases (VPDs), impact of the vaccination on future epidemiology of VPDs are taken into account. The focus and objectives are different when planning vaccination strategies for a large community and for an individual child. For instance, an optimal and not necessarily best immunological response may be considered appropriate for effective protection at the earliest in a situation where risk of contracting infection at an early age is high. The few key determinants of an optimal immunization schedule include the following:

**Immunological determinants** Minimum age at which vaccine elicits immune response, the total number of doses required for adequate priming, duration of protection, need and timing of boosters, interval between doses, if multiple doses are required, are few examples where immunological principles affect structure of an immunization schedule.

**Epidemiological determinants** Disease burden and age of highest susceptibility for infection and disease, impact of vaccination on age shift of a particular disease, propensity of a vaccine to cause herd effect, determination of ideal coverage to offset disease transmission, force of transmission ( $R_0$ ) of a particular VPD in different geographic regions, impact of vaccination on postvaccination disease epidemiology, are few instances that determine planning and execution of a mass vaccination program.

**Programmatic determinants** Logistic issues including overall financial burden and cost-effective analysis, opportunity to deliver an antigen with other scheduled intervention, increase coverage by limiting the required contacts, transportation and maintenance of vaccines in proper cold chain, training of health staff, gain critical significance whenever a large scale, mass vaccination program is devised.

A fair interplay of the above three determinants ultimately have major impact on the designing of an optimal immunization schedule. Some other key factors such as immune-competence of the individual, age-specific risk for disease, age-specific risk of disease complications, potential interference with maternal antibodies, and interaction with other vaccines in the schedule also affect the scheduling of different vaccines.

### Synergizing Between Immunological and Epidemiological Determinants

Striking a fair balance between immunological principles and epidemiological concerns is the biggest challenge to devise an optimal immunization schedule. Issue like achieving protective immune response prior to the age when children are most vulnerable versus inducing optimal immune response causes greatest concern. Starting late might induce a higher response, but miss the vulnerable age. For example, the current expanded program on immunization (EPI) schedule of 6-10-14 weeks for primary doses of DTP, *Haemophilus influenzae* type b (Hib), and Hepatitis B followed in most developing countries including India, is not ideal immunologically, but considering the epidemiology of these VPDs which affect children at very young age, this schedule is most suitable. Similarly, wider intervals between doses give a better response, but delays induction of immunity, leaving children vulnerable in a crucial period of life. For example, the schedule of 2, 4, 6 months followed in most industrialized countries, is immunologically much superior to EPI schedule but may not be ideal for developing countries having younger age affection of most VPDs. Hence, the disease epidemiology factors in a big way while forming an immunization schedule, particularly at country level. A schedule that is used in one population is not the best for another; hence, the need to individualize and tailor to suit local needs.

### Determinants of Vaccination Schedules for Community Versus Individual Protection

While planning and developing a vaccination program or schedule, a multifactorial approach is preferred in decision making. Vaccination schedules at individual and community level often vary considerably with regard to different attributes as summarized in **Table 1**. Large scale mass vaccination programs are in the best interests of the community and at Government's cost whereas vaccination provided through private health-care is in the best interests of each child. Therefore the cost is to be borne by the family. So epidemiological and economic parameters go into the assessment of the promise and potential of specific vaccines in delivered through public health program. As shown in **Table 1**, for public sector programs usually it is cost first, efficacy next followed by safety. However, at individual level, it is safety first, efficacy next followed by cost. Nevertheless, it must be remembered that what is not in the best interests of the individual cannot be in the best interests of the community and what is in the best interests of the community is also in the best interests of the individual. Therefore, the private health-care and public health programs including vaccination schedules should be complementary and not contradictory regarding immunological basics, ethics and epidemiology.

### Vaccination Schedule for Community Protection

While designing a vaccination schedule for the community, the greatest challenge comes on the programmatic front. Creating synergies between immunological and epidemiological considerations is one of the greatest hurdles to pass. Matching the optimal schedule with programmatic realities in the local population to achieve maximum effect on disease control is the key consideration. Various logistic issues such as predominant modality of vaccine delivery, e.g., fixed sites or outreach, number of contacts required with health systems, exploring options of linking vaccination with delivery of other interventions, exploring best delivery mechanism (such as campaigns, immunization days, etc.) that increase coverage and reach the *hard to reach*

**Table 1** Key differences in the vaccination schedules devised for community and individual protection

Attributes	Community/Public health	Individual/Private health-care
Focus	Community; Vaccination in public health is in the best interests of community	Individual child; Vaccination in health-care is in the best interests of each child
Need	Determined by the epidemiology and disease burden in the community	Determined by the risk (probability of disease) to an individual child
Objective	To control a set of infectious diseases from the community Control = reduce <i>incidence</i> and <i>monitor</i> reduction	To protect the individual who is vaccinated
Ownership	Government	Consulting physician/pediatrician or individual health facility
Volume	Large	Small
AEFI	Mainly <i>coincidental</i> and <i>programmatic</i> since large volume is used	Mainly <i>vaccine reactions</i> and <i>coincidental</i>
Funding	By the government or international donor agencies	Individual parents
Logistic issues	Major determinants	Not so important
Considerations	Cost first, efficacy next, safety last	Safety first, efficacy next, cost last
Examples	EPI and Universal Immunization Program (UIP)	IAP Immunization schedule

areas, are taken into consideration. In a nutshell, the issues related to coverage, cost, compliance, availability, disease burden, competing priorities, funding, and competing interests play major determinants for vaccination schedules for community protection.

### Vaccination Schedule for Individual Protection

Safety and immunological issues override other considerations while a schedule is designed for individual protection. Sharing information with parents is one of the key factors. Here, the *actors* are not many, and they are mainly parents and physicians. Whereas many actors such as Ministry of Health, WHO, finance department, funding agencies, professional academic bodies, play important role in vaccination schedule for community protection. So a vaccination schedule targeting individual child may be closer to established immunological principles, but it should not be contradictory to national vaccination schedule for community protection and should also address the epidemiological concerns.

## NATIONAL IMMUNIZATION PROGRAMS

At country level vaccination programs, there are two main aims, first to prevent serious disease (in absolute numbers, severity or both), and second to reduce spread of infection. Once a disease gets eliminated, the objectives of vaccination against that particular VPD also change as is the case with polio in India. During pre-elimination, endemic phase, the objective was to control disease and prevent paralysis caused by wild poliovirus. Safety concerns of oral polio vaccine (OPV) took backseat and issues such as vaccine-associated paralytic polio (VAPP) were not highlighted. Once the elimination of wild poliovirus is achieved, the objective has shifted to maintain immunity against wild poliovirus and safety issues of OPV came into perspective. **Table 2** summarizes the shifting focus and key objectives in the two stages.

### Requirements of an Ideal Vaccination Schedule

Apart from meeting epidemiological and immunological concerns, an ideal vaccination schedule whether designed for community or individual protection should have provision for *catch-up* immunization for those who missed age-recommended vaccine dose. Further, there is a need to reach age groups beyond infancy with high coverage. Detailed guidelines regarding minimum number of doses in different age groups and minimum intervals between two doses of a vaccine shall facilitate catch-up immunization. Immunization of adolescents at community level is a grossly neglected entity. A separate schedule for adolescents and preadolescents can fill this void.

Immunization is a dynamic and very rapidly evolving subspecialty of science. New developments such as licensing of new vaccines and emergence of new technology on vaccine administration and storage are taking place regularly at short intervals, hence the need to revise recommendations at regular interval. An ideal schedule cannot be static but should be flexible enough to incorporate new developments including new vaccines into the schedule.

*Factors that affect the inclusion of a new vaccine in the national immunization program:*

1. Disease (burden, severity, mortality, national security, risk of importation, competing priorities)
2. Recipient (age, cohort size, politics)
3. Vaccine (local production, availability, cost, efficacy, safety, other vaccines)
4. Cost-effectiveness analysis.

In countries still having a high burden of natural disease, disease prevention and controlling the morbidity and mortality is the most important objective, therefore vaccine with the highest effectiveness is chosen for inclusion in the national program.

**Table 2** Aims and objectives of vaccination programs during various stages of VPD control

	Countries where disease is endemic	Countries where disease has been eliminated
Objective	Disease control	Maintain immunity
Concerns	Medical, political and economic	Importation, outbreaks, bioterrorism
Choice	Vaccine that meets specific criteria (may not always be the safest option)	Vaccine with the highest safety
Example	OPV in Global Polio Eradication Initiative	IPV during polio endgame and posteradication phase

Abbreviations: VPD, vaccine-preventable diseases; IPV, inactivated poliovirus vaccine; OPV, oral polio vaccine.

Whereas, in a country with a low burden of natural disease, the main concerns are low or no side effects of a new vaccine which will decide acceptance of the vaccine. Therefore, a vaccine with a high safety level can only be included in the immunization schedule. As new vaccines are being developed, they are being incorporated in the immunization schedule based on the disease burden and cost-effectiveness of the vaccine.

Strict compliance to *evidence-based review* process while issuing recommendations on vaccination schedule is another key requirement of an ideal vaccination schedule. Most of the reputed international agencies such as WHO, ACIP, etc. have now incorporated *evidence-based review* policy and have also started adopting GRADE (Grading of Recommendations Assessment, Development and Evaluation) system on rating quality of evidence and strength of recommendations.

## VACCINATION SCHEDULES AT GLOBAL, REGIONAL AND NATIONAL LEVEL

There is great heterogeneity in the vaccination schedules of developing and developed countries. Even in these two broad groups, different vaccines and different schedules of same vaccines are noticed based on the availability of licensed products in a particular country and their need based on epidemiology of different VPDs (**Box 1**). There are several reasons why uniform immunization schedule is not possible; some of them include the following:

- *Epidemiologic heterogeneity*: Increasing reports of resistant, emerging and re-emerging infections that challenge vaccination strategies
- *Resource heterogeneity*: Priorities have to be affixed commensurate to affordability
- Variable health systems capacity and research evidence
- Variability in ethics, legal and policy procedures
- Variations in public and political reactions: AEFI, agenda, intensities of resistance and hostility.

### Process of Issuing Global Recommendations

WHO issue recommendations to each country, particularly to developing country on broad framework of their own country-specific vaccination schedule. WHO has formed a specific, highly technical group on immunization, called Strategic Advisory Group of Experts (SAGE) on immunization. SAGE is the principal advisory group to WHO for issuing recommendations on vaccines and immunization related issues that ultimately decide overall global policies and strategies.

The WHO encourages each of its country members to have their own NITAGs (National Immunization Technical Advisory Groups) to decide and chalk out their own national immunization programs and vaccination schedules. Each NITAG is expected to follow WHO-SAGE recommendations on immunization-related issues. The NITAG in India was first established by Ministry of Health, Government of India in August, 2001 and is called as NTAGI (National Technical Advisory Group on Immunization).

#### BOX 1 Different vaccination schedules of few key developing countries

*Vaccination schedules for primary immunizations in developing countries:*

- 6, 10, 14 weeks (India, Kenya, Madagascar, Mozambique, Philippines, Rwanda, South Africa)
- 2, 4, 6 months (Egypt, Chile, Mexico, Thailand, Uruguay, Argentina, Brazil)
- 2, 3, 4 months (Gambia, Indonesia, Turkey, Vietnam)
- 2, 3, 5 months (Malaysia)
- 3, 4, 5 months (China).

NTAGI issues recommendations to Government of India to formulate national immunization schedule and also to make changes based on new developments. There is another vaccination schedule issued by Indian Academy of Pediatrics (IAP) for its members and clinicians in the private sector. The Academy has a specific subcommittee, ACVIP (Advisory Committee on Vaccines and Immunization Practices) that issues recommendations regarding vaccination schedule at periodic intervals. So, in India there are two major vaccination schedules in practice today, one, the vaccination schedule under Universal Immunization Program (UIP) issued by Government of India (**Table 3**), another, by Indian Academy of Pediatrics (**Table 4**).

## NEED OF THE HOUR

There are still many challenges both at planning and execution level as far as national immunization program and UIP schedule is concerned. Many key vaccines are still not part of our national immunization schedule, and on the other end, there is gross heterogeneity of coverage in different states and even in different districts of the existing vaccines. Further, there is inappropriate delivery of vaccines. The states having the highest burden of VPDs are reached in the last owing to poor infrastructure and vaccine delivery system. There is an urgent need of research and analysis to explore more cost-efficient schedules, particularly with new vaccines. There is need to reach age groups beyond infancy with high coverage, to incorporate vaccines for certain *neglected* diseases such as typhoid, rabies, etc., need to national level up scaling of pentavalent vaccines, to develop schedules and strategies to reach the *hard-to-reach* areas, to create links with other programs to achieve synergy and to deliver a package of interventions, etc. The bolstering of *school health programs* to boost adolescent immunization is also urgently needed. In the last, there is growing demand on relook at the existing EPI schedule in India and other developing countries.

### IN A NUTSHELL

1. Proper scheduling of available vaccine is the key to proper utilization of available vaccines and achieving good protection against prevailing VPDs.
2. The few key determinants of an optimal immunization schedule include immunological principles, epidemiological aspects and programmatic issues.
3. There are key differences in the vaccination schedules designed for individual and community protection.
4. While safety and efficacy are the key issues for individual schedule, cost and programmatic issues override all the considerations in schedules planned for community protection.
5. There is marked heterogeneity in the vaccination schedules of different countries.
6. WHO-SAGE gives recommendations to NITAGs of individual country to formulate their national vaccine policies including their schedules.
7. NTAGI in India gives recommendations to Government of India regarding planning of its immunization schedule. ACVIP of IAP devises its immunization schedule for pediatricians working in private sector.
8. Catch-up immunization, adolescent immunization, improvement in coverage, adoption of new vaccine technology, incorporation of new lifesaving vaccines, support to innovation and research and development related to vaccines are few key initiatives urgently needed to improve our existing national immunization schedule.

**Table 3** Vaccination schedule under Universal immunization program (UIP) in India

<i>Vaccine</i>	<i>When to give</i>	<i>Dose</i>	<i>Route</i>	<i>Site</i>
<i>For Pregnant Women</i>				
TT-1	Early in pregnancy	0.5 mL	Intramuscular	Upper arm
TT-2	4 weeks after TT-1*	0.5 mL	Intramuscular	Upper arm
TT-Booster	If received 2 TT doses in a pregnancy within the last 3 years	0.5 mL	Intramuscular	Upper arm
<i>For Infants</i>				
BCG	At birth or as early as possible till 1 year of age	0.1 mL (0.05 mL until 1 month of age)	Intradermal	Left upper arm
Hepatitis B Birth dose	At birth or as early as possible within 24 hours	0.5 mL	Intramuscular	Anterolateral side of mid-thigh
OPV Zero dose	At birth or as early as possible within the first 15 days	2 drops	Oral	Oral
OPV 1, 2 and 3	At 6 weeks, 10 weeks and 14 weeks	2 drops	Oral	Oral
DPT 1, 2 and 3	At 6 weeks, 10 weeks and 14 weeks	0.5 mL	Intramuscular	Anterolateral side of mid-thigh
Hepatitis B 1, 2 and 3	At 6 weeks, 10 weeks and 14 weeks	0.5 mL	Intramuscular	Anterolateral side of mid-thigh
HiB 1, 2 and 3	At 6 weeks, 10 weeks and 14 weeks	0.5 mL	Intramuscular	Anterolateral side of mid-thigh
Measles 1st dose	9 completed months–12 months. (give up to 5 years, if not received at 9–12 months age)	0.5 mL	Subcutaneous	Right upper arm
JE 1st dose**	9 completed months	0.5 mL	Subcutaneous	Left upper arm
<i>For Children and Adolescents</i>				
DPT booster	16–24 months	0.5 mL	Intramuscular	Anterolateral side of mid-thigh
OPV Booster	16–24 months	2 drops	Oral	Oral
Measles 2nd dose	16–24 months	0.5 mL	Subcutaneous	Right upper arm
Rubella ***	16–24 months Adolescent girls	0.5 mL	Subcutaneous	Right upper arm
JE 2nd dose	16–24 months with DPT/OPV booster	0.5 mL	Subcutaneous	Left upper arm
DPT Booster 2	5–7 years	0.5 mL	Intramuscular	Upper arm
TT	10 years and 16 years	0.5 mL	Intramuscular	Upper arm
Vitamin A****				

\*Give TT-2 or Booster doses before 36 weeks of pregnancy. However, give these even if more than 36 weeks have passed. Give TT to a woman in labor, if she has not previously received TT.

\*\*JE Vaccine (SA 14-14-2) is given in select endemic districts, after the campaign is over in that district.

\*\*\* Rubella vaccine will be given as part of Measles 2nd dose.

\*\*\*\*The 2nd to 9th doses of vitamin A can be administered to children 1–5 years old during biannual rounds, in collaboration with ICDS.

Abbreviations: BCG, bacillus Calmette–Guérin; DPT, diphtheria, tetanus and pertussis; Hib, *Haemophilus influenzae* type b; JE, Japanese encephalitis virus.

2 years	Typhoid booster	<ul style="list-style-type: none"> <li>Either Typbar-TCV® or Vi-polysaccharide (Vi-PS) can be employed as booster</li> <li>Typhoid revaccination every 3 years, if Vi-polysaccharide vaccine is used</li> <li>Need of revaccination following a booster of Typbar-TCV® not yet determined</li> </ul>
4–6 years	DTwP B2/DTaP B2 OPV 3 Varicella 2 Typhoid booster	<b>Varicella</b> The 2nd dose can be given at any time 3 months after the 1st dose
10–12 years	Tdap/Td HPV	<b>Tdap</b> It is preferred to Td followed by Td every 10 years. <b>HPV</b> <ul style="list-style-type: none"> <li>Only 2 doses of either of the two HPV vaccines for adolescent/preadolescent girls aged 9–14 years</li> <li>For girls 15 years and older, and immunocompromised individuals 3 doses are recommended</li> <li>For two-dose schedule, the minimum interval between doses should be 6 months</li> <li>For 3 dose schedule, the doses can be administered at 0, 1–2 (depending on brands) and 6 months</li> </ul>
<b>II. IAP recommended vaccines for high-risk* children (Vaccines under special circumstances):</b>		
1-Influenza vaccine 2-Meningococcal vaccine 3-Japanese encephalitis vaccine 4-Cholera vaccine 5-Rabies vaccine 6-Yellow fever vaccine 7-Pneumococcal polysaccharide vaccine (PPSV 23)		

**\* High-risk category of children:**

- Congenital or acquired immunodeficiency (including HIV infection)
- Chronic cardiac, pulmonary (including asthma, if treated with prolonged high-dose oral corticosteroids), hematologic, renal (including nephrotic syndrome), liver disease and diabetes mellitus
- Children on long-term steroids, salicylates, immunosuppressive or radiation therapy
- Diabetes mellitus, cerebrospinal fluid leak, cochlear implant, malignancies
- Children with functional/anatomic asplenia/hyposplenia
- During disease outbreaks
- Laboratory personnel and health-care workers
- Travelers
- Children having pets in home
- Children perceived with higher threat of being bitten by dogs such as hostellers, risk of stray dog menace while going outdoor.

**Abbreviations:** BCG, bacillus Calmette Guérin; DTaP, diphtheria tetanus acellular pertussis; DTwP1, diphtheria tetanus whole-cell pertussis; Hib, *Haemophilus influenzae* type b; HPV, human papillomavirus; IPV, inactivated poliovirus vaccine; MMR, measles-mumps-rubella; OPV, oral polio vaccine; PCV, pneumococcal conjugate vaccine; RV, rotavirus vaccine; SIA, supplementary immunization activities; Tdap, tetanus, diphtheria and pertussis.

## Chapter 23.4

# Vaccine Storage and Cold Chain

Karan Singh Sagar, Manish Jain

Safety and potency are the two key characteristics underlying success of any vaccine resulting in reduction in incidence of vaccine preventable diseases (VPDs) and associated mortality and morbidity. These key characteristics are in most part dependent on and determined by proper management of vaccines and vaccine products, which includes storage in the recommended conditions and handling during transportation, distribution and use. The exposure of vaccines (and vaccine products) to temperature (and light) outside the recommended ranges may lead to reduction in potency and the protection it results after administration to the beneficiaries. This not only leads to improved immunization safety and efficacy but also serves to reduce program costs by preventing high wastage rate.

**Cold chain** It is the system used for storage and transportation of vaccines (and vaccine products) in the recommended conditions and acceptable temperature ranges from point of manufacture until it is administered to the beneficiary (**Fig. 1**). Effective cold chain network is the backbone for ensuring quality immunization services in any country. The key elements of cold chain system include: personnel (for vaccine management, storage and distribution), equipment (for vaccine storage and transportation, both electrical and nonelectrical) and procedures including monitoring (for ensuring vaccine storage and transportation under recommended conditions).

### TERMINOLOGY USED IN COLD CHAIN SYSTEM

**Hold over time of cold chain equipment** It is the time in hours for which all points inside the vaccine compartment of a vaccine

refrigerator remain below  $+10^{\circ}\text{C}$ , at the maximum ambient temperature of the temperature zone for which appliance is rated, after the power supply has been disconnected. For example, the minimum storage temperature of an ice-lined refrigerator (ILR) is  $+2^{\circ}\text{C}$ , so the time taken for cabinet temperature to reach  $+10^{\circ}\text{C}$  would be the hold over time of that ILR. In case of vaccine freezers, the hold over time is the time in hours for which the temperature inside the compartment remains below  $-5^{\circ}\text{C}$ . The hold over time applies to both electrical and nonelectrical cold chain equipment, and for a specific equipment, it depends on the ambient temperature (with inverse relationship), frequency of opening the equipment, quantity of vaccines stored, spacing between vaccine boxes and condition of water-packs (in nonelectrical equipment).

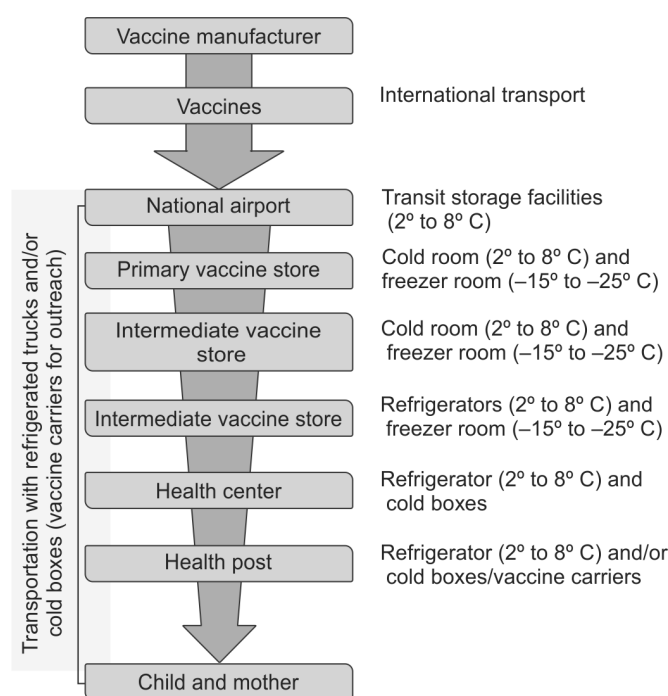

**Vaccine storage capacity** It is the actual volume available inside the equipment (refrigerator, freezer, cold box or vaccine carrier) for the storage of vaccines. This is specified by the equipment manufacturer in the product specifications and can also be measured by physical methods.

**Water-pack freezing capacity** This applies to water-pack freezers and is the maximum weight (kg/24 hour) of water-packs that can be fully frozen, in one batch, within a period of 24 hours.

**Refrigerants and foaming agents [Chlorofluorocarbons (CFC)]** R11 and R12 have been popular refrigerant gases used in compression refrigeration circuits and as foaming agents for the insulation of refrigerators, cold boxes and vaccine carriers. But as these are potent greenhouse gases having depleting effect on stratospheric ozone layer, therefore as per *Montreal Protocol* CFC equipment are condemned for use in industrialized nations (since January 1st, 1996) as well as in the developing nations (since January 1st, 2010). Refrigerants now recommended and which are now being used by manufacturers include hydrofluorocarbon (HFC) 134a and hydrocarbon R600 (isobutene); and the foaming agents that are being used are cyclopentane and R141b. Other gases being investigated for these purposes are HPC-245fa, HFC-365mfc, HFC-234a, isopentane and *n*-pentane.

**Vaccine wastage factor** This indicates how much additional vaccine should be ordered in order to allow for the given wastage rate. The vaccine wastage rate can vary according to session size, session plan, vial presentation, supply management and many other characteristics. Each country should monitor its own vaccine wastage; however, there are indicative wastage levels for different vial sizes for lyophilized (single dose: 5%; 2–6 dose vial: 10%; 10–20 dose vial: 50%) and liquid vaccines (single dose: 5%; 2–6 dose vial: 10%; 10–20 dose vial: 25%). Vaccine wastage can be due to unavoidable and avoidable reasons. Wastage occurring due to discarding reconstituted vaccines at the end of session or after recommended usage time, poor stock management leading to oversupply, wastage due to expiry before use, failure of cold chain leading vaccines to exposure to higher or lower temperature, administering incorrect dosage to the beneficiaries, failure in using multidose vials in correct manner and breakage, etc. are the important avoidable reasons which can be addressed through proper planning and compliance to guidelines.

**Volume per dose** This refers to the volume occupied by each dose of vaccine, including the volume occupied by its packaging (and volume of diluent, if applicable) in the cold chain equipment at time of storage. The volume per dose depends on the type of vaccine and is an important factor to be considered for estimation of vaccine storage requirements.

**Figure 1** Cold chain

Source: Immunization in Practice, Module 3, WHO. (2008)

### VACCINE STORAGE IN COLD CHAIN

Each vaccine is different in terms of its constituents and therefore each one of them have a recommended range of temperature for storage and transportation, clearly specified in the product

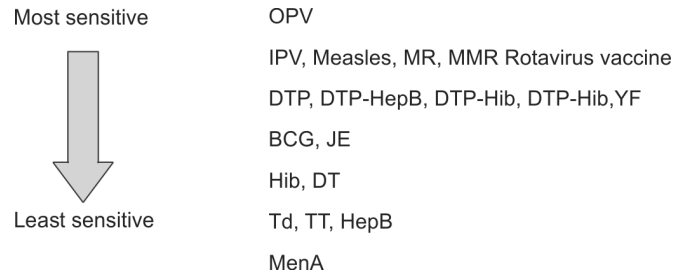

specifications issued by the manufacturer. Temperature ranging from +2°C to +8°C is generally safe for storage of majority of vaccines, except a few which need to be stored at negative temperature between -15°C and -25°C [e.g., oral polio vaccine (OPV)]. Vaccines exposed to temperature above +8°C gradually lose their potency over time. This can be either in form of an exposure to lot of heat over a short period of time (e.g., keeping vaccine in direct sunlight on a summer day) or exposure to small amount of heat over a longer period of time (e.g., frequent opening the lid of storage equipment). Heat-sensitive vaccines are shown in **Figure 2**. There are some vaccines, e.g., “T” series vaccines [e.g. diphtheria tetanus pertussis (DTP), diphtheria tetanus (DT), tetanus toxoid (TT), dT, Td and Hepatitis B], liquid *Haemophilus influenzae* type b (Hib) and liquid pentavalent vaccine, which are damaged by freezing and/or exposure to freezing temperature. Hepatitis B vaccine is most sensitive to the freezing temperature. Freeze sensitivity of vaccines is shown in **Figure 3**.

There are some vaccines which are sensitive to strong light. These vaccines lose their potency overtime followed by exposure to ultraviolet component of sunlight and fluorescent (neon) light. Such vaccines are packaged and supplied in vials having dark-brown glass which gives some protection from damage due to light exposure, but still care must be taken to keep them covered and protected from strong light during storage, transportation and use. Examples of these types of vaccines are bacille Calmette-Guérin (BCG), measles and rubella (MR), measles, mumps, and rubella (MMR) and rubella, which are sensitive to both light and heat.

Diluents used for reconstitution of freeze dried vaccines may be stored outside the cold chain as it may occupy the space inside equipment which is necessary for storage of vaccines but at the same time, it is important that diluents are stored between +2°C to +8°C inside storage equipment/refrigerator at least 24 hours before use, i.e., reconstitution. Same temperature of vaccine and diluent prevents thermal shock to the vaccine, i.e., death of some or all the essential live organisms in the vaccine due to exposure to higher temperature leading to reduction in potency. Besides this, it is essential that only the diluent supplied by manufacturer either bundled with vaccine or separately should be used for reconstituting freeze dried vaccine, because diluents are specifically designed with respect to volume, pH level and chemical properties to suit for the needs of a particular vaccine.

The physical appearance of any vaccine cannot help to decide, if it has been exposed to high or freezing temperature, or to strong light as the appearance of vaccine generally remains unchanged. Once any vaccine gets damaged due to inappropriate temperature exposures, it is not possible to regain its potency. Vaccine vial monitor (VVM) and freeze tags are generally used in cold chain to assess exposure of vaccines to higher or freezing temperature over a period of time. The details of VVM and freeze tags are as follows:

**Vaccine vial monitor (VVM)** This is a tag containing a heat sensitive material and placed on label or on the cap of the vaccine vials (for liquid and freeze dried vaccines respectively). It is designed to register cumulative heat exposure over time during transportation and/or storage. VVM conventionally comprise of an inner lighter square placed within outer darker circle. The combined effects of temperature and duration of exposure cause the inner square of VVM to darken gradually and irreversibly. As long as inner square of VVM is lighter than the outer circle (and the expiry date has not passed) the vaccine is usable; but when color of inner square matches with that of outer circle (known as discard point) or gets darker the vaccine becomes unusable. There are four types of VVM currently in use—types 2, 7, 14 and 30, each number referring to the number of days the VVM takes to reach discard point, if kept at +37°C. Different types of VVM are used to monitor different vaccines depending on their heat sensitivity. For example, VVM

**Figure 2** Heat sensitivity of different vaccines

**Abbreviations:** BCG, bacille Calmette Guérin; DT, diphtheria tetanus; DTP, diphtheria-tetanus pertussis; MR, measles and rubella; MMR, measles, mumps, rubella; HepB, hepatitis B; Hib, *Haemophilus influenzae* type b; IPV, inactivated poliovirus; OPV, oral polio vaccine; Td, tetanus diphtheria; TT, tetanus toxoid; MenA, meningococcal A; YF, yellow fever.

**Figure 3** Freeze sensitivity of different vaccines

**Abbreviations:** DT, diphtheria tetanus; DTP, diphtheria-tetanus pertussis; HepB, hepatitis B; Hib, *Haemophilus influenzae* type b; IPV, inactivated poliovirus; Td, tetanus diphtheria; TT, tetanus toxoid; YF, yellow fever.

type 2 is assigned to OPV, which is the most heat sensitive vaccine, while VVM type 14 is assigned to DTP-Hep B, which is much less heat sensitive. VVM, however, have its limitations as it only measures exposure to high temperature and not vaccine potency, safety and exposure to freezing temperature (for freeze sensitive vaccines). Secondly, status of VVM only applies to the vaccine vial on which it is tagged, but is not applicable as a proxy indicator for other vaccines, which may have different temperature sensitivities and storage history. It is important that all workers who manage, handle and administer vaccines are well aware of different stages (usable and unusable) of VVM.

**Freeze indicator** These are electronic and passive phase change type of devices used during internal distribution of freeze sensitive vaccines and for monitoring freezing events in cold rooms and refrigerators. The status of freeze indicator changes from *good* to *alarm* as soon as vaccine is exposed to -0.5°C for more than 60 minutes. These indicators are used to assess status of freeze sensitive vaccines.

Before distributing, opening or using any vaccine, it is important to monitor status of VVM and expiry date. Vaccines whose expiry date has passed should never be used (even if VVM shows no heat damage), and on the other hand, vaccine vials whose VVM has crossed the discard point should not be used even, if they are well within the expiry date. Similarly, usable status of freeze sensitive vaccines can be determined by *Shake test*. This test is not routinely employed and is done only for suspected vaccine vials, to assess whether at any point of time they have been exposed to freezing temperature. *Shake test* compares the *test* vial of the vaccine which is suspected to have frozen during storage or transportation with a *Control* vial of the same type of vaccine and from the same manufacturer and same batch number. *Control* vial is prepared by storing it at -20°C overnight, and later allowed to thaw at normal room temperature. During test both *Test* and *Control* vials are vigorously shaken and placed cap side down on

flat surface undisturbed for 30 minutes. The rate of sedimentation is observed in both the vials. If the rate of sedimentation in *Test* vial is slower than in the *Control* vial shows that the vaccine under test has not been damaged due to freezing. However, if the sedimentation in both vials is same or is faster in the *test* vial than the vaccines has been damaged and should not be used.

Total period of vaccine storage at different levels of entire cold chain system is also an important factor for proper vaccine management. Suggested maximum length of storage of vaccines at national level is 6–12 months and that at subnational and district level stores is 3 months, maximum. At sub-district and health facility levels vaccines should not be stored for period of more than 1 month. **Table 1** lists the recommended ranges of storage temperature for most Expanded Programme on Immunization (EPI) vaccines.

## COLD CHAIN EQUIPMENT

There is a wide range and variety of equipment available as part of cold chain system having different capacities and features to suit the local conditions and needs. Electrical cold chain equipment includes Walk-in-Coolers (WIC), Walk-in-Freezers (WIF), Deep Freezers (DF), Ice-lined Refrigerators (ILR) and domestic refrigerators; while nonelectrical cold chain equipment are cold boxes, vaccine carriers and water-packs. There are also solar refrigerators for areas with poor or no electricity supply. Refrigerated trucks and vaccine vans are also part of cold chain system and are used for transportation in the recommended temperature ranges, which help to ensure vaccine potency from manufacturer till health facilities, outreach sessions and beneficiaries.

## Electrical Cold Chain Equipment

**Walk-in-freezers** These are installed at large stores at national and subnational levels and are used to store bulk quantity of vaccine for longer period (3 months or more), maintaining temperature around  $-20^{\circ}\text{C}$ . Generally, these are used for storing OPV and for preparing frozen water-packs to be used during transportation, campaigns, etc. These are available in different sizes and are provided with two cooling units and an auto-start generator for maintaining temperature in case of power failure/interruption. Along with this, WIF also have automatic temperature recording system and emergency alarm which sets on if the temperature crosses a safe range.

**Walk-in-coolers** These are installed at national and subnational level stores and are used to store bulk quantity of vaccines at  $+2^{\circ}\text{C}$  to  $+8^{\circ}\text{C}$  for a longer period (3 months or more). These are used to store vaccines such as pentavalent, PCV, Rota, DTP, DT, TT, measles, BCG and Hepatitis B, etc. and similar to WIF, these also have two cooling units, autostart generator, automatic temperature recording system and emergency alarm.

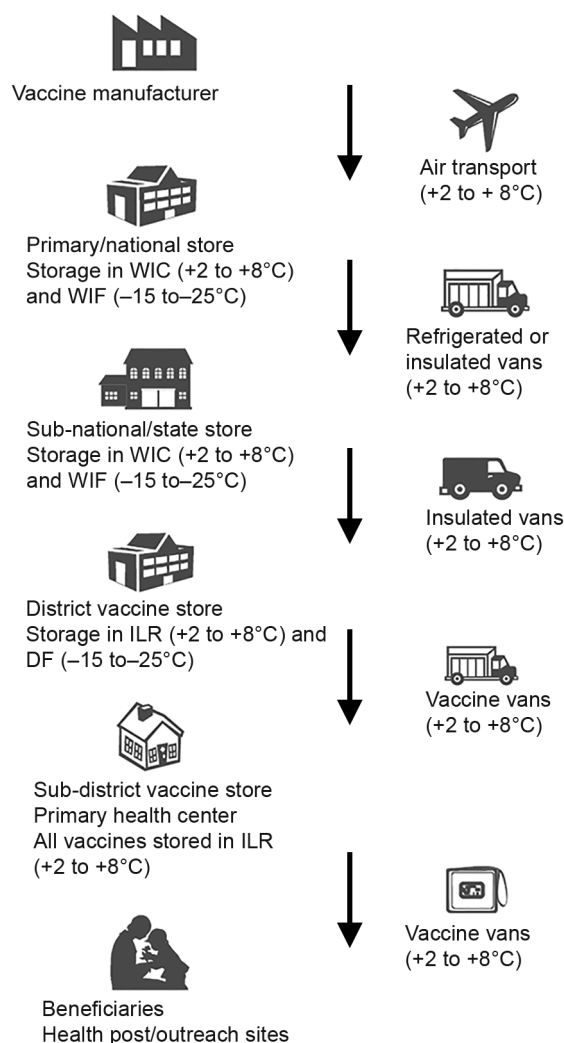

**Deep freezers** These are used at district and sub-district level and are used for storing vaccines (mostly OPV) and for preparing/freezing water-packs. In immunization program, different sizes of top-opening freezers are supplied as they are able to retain cool air inside better than the front opening refrigerators. Deep freezers maintain a cabinet temperature in the range between  $-15^{\circ}$  and  $-25^{\circ}\text{C}$ . In cases of power failure, which is very common in subdistrict level remote and rural health facilities, the special insulation of these freezers can maintain the cabinet temperature in the range of  $-15^{\circ}$  to  $-25^{\circ}\text{C}$  for a period up to 18 and 26 hours at external ambient temperatures of  $42^{\circ}$  and  $32^{\circ}\text{C}$  respectively, if not opened.

**Ice-lined refrigerators** These are top opening electrical cold chain equipment available in different sizes and are used to store vaccines at district and sub-district level facilities at  $+2^{\circ}$  to  $+8^{\circ}\text{C}$  storage temperature (**Fig. 4**). These are internally lined with water containers (water-packs or tubes in different models) fitted around the walls in form of a frame. The water in these containers freeze when the ILR is functioning (or when power supply is available), and in case of power failure/interruption this ice or cold water in the containers maintain the storage temperature within the recommended range for at least 20 hours (hold over time), if not opened. This characteristic feature of ILR makes it suitable for vaccine storage even in the areas having electricity supply of as less as 8 hours. For areas with no power supply, ILRs are designed to run using kerosene, gas and also solar energy. The bottom part of the ILR is the coldest part internally and therefore vaccines which can get damaged by freezing or exposure to low temperature should not be kept in this part, especially directly on floor (Remember—freeze-sensitive vaccines should *never* be stored within 150 mm of the base). The top part maintains the recommended temperature range and all vaccines can be stored safely in this part. As a safety measure, it is necessary to ensure during storage that none of the vaccine vials comes in direct contact with the walls or floor which can lead to freeze damage.

**Table 1** Recommended ranges of storage temperature for vaccines

Vaccines	National level stores	State and district level stores	Health facility level
	Maximum duration of storage: 6–12 months	Maximum duration of storage: 3 months	Maximum duration of storage: 1 month
OPV	Store at $-15^{\circ}\text{C}$ to $-25^{\circ}\text{C}$ OPV is the only vaccine that can be safely be frozen and unfrozen repeatedly		Store at $+2^{\circ}\text{C}$ to $+8^{\circ}\text{C}$
BCG, measles, MMR, MR, yellow fever, Hib lyophilized, meningitis, JE	These lyophilized vaccines are to be stored at $+2^{\circ}\text{C}$ to $+8^{\circ}\text{C}$ Under exceptional circumstances, these can be temporarily stored at $-15^{\circ}\text{C}$ to $-25^{\circ}\text{C}$ (e.g., if there is temporary shortage of storage space) Diluent never to be frozen		Store at $+2^{\circ}\text{C}$ to $+8^{\circ}\text{C}$
HepB, DTP-HepB, DTP-HepB-Hib liquid, Cholera, Hib liquid DTP, DT/TT/Td Pneumococcal, Rotavirus, HPV, Pneumococcal, Rabies, Influenza, IPV		Store at $+2^{\circ}\text{C}$ to $+8^{\circ}\text{C}$ Never freeze	

**Abbreviations:** BCG, bacillus Calmette Guérin; DT, diphtheria tetanus; DTP, diphtheria-tetanus pertussis; MR, measles and rubella; MMR, measles, mumps, rubella; HPV, human papillomavirus; HepB, hepatitis B; Hib, *Haemophilus influenzae* type b; IPV, inactivated poliovirus; JE, Japanese encephalitis; OPV, oral polio vaccine; Td, tetanus diphtheria; TT, tetanus toxoid.

**Figure 4** Cold chain system

**Domestic refrigerators** This can also maintain a temperature within the recommended ranges but the hold over time of these refrigerators is as little as four hours, and their capacity to freeze water-packs is also limited due to which they are generally not recommended in the immunization program. These are mostly used for vaccine storage in small health facilities and by private service providers in the urban settings where continuous power supply can be ensured. In settings where the domestic refrigerators are used for storing vaccines, it is necessary to ensure that other supplies (e.g., drugs, ointment, pathological samples, food articles and drinks) are not placed inside it and that they are exclusively used and labeled for storage of vaccines, diluents and water-packs only. Secondly, the vaccines must not be stored in the door shelves (which are relatively warmer and gets exposed to environment temperature every time when door is opened) and in the freezer compartment (which should be used only for freezing and storing water-packs). Vaccines should be arranged in shelves from top to bottom in order of their heat sensitivity, i.e., vaccines which are more heat sensitive (e.g., OPV and measles) should be placed just below the freezer compartment, while more freeze-sensitive vaccines (e.g., Hepatitis B and T series vaccines) should be in the lower shelves. Diluents should also be placed next to the vaccines for which they are supplied so that they both are at the same temperature at time of distribution and this minimizes any chances of mixing up with diluents for other vaccines.

**Sure chill vaccine refrigerators** These are new type of refrigerators which are specifically designed to maintain temperature range of 4°C–5°C for vaccines and avoid any chances of freezing and exposure to higher temperature. These are now available in two types—one running on electricity (requiring just 2½ hours of power supply per day) and the other solar *direct drive* model (with no requirement of batteries to maintain cooling performance overnight). These refrigerators can keep vaccines safe for up to 10 days at 32°C ambient, and even longer at lower temperature.

**Solar refrigerators** These are freezer cum refrigerators with two separate compartments, one having basket for storing vaccines (maintains temperature at +2°C to +8°C) and other for freezing water-packs (with temperature at -15°C to -25°C). These refrigerators run on the same principle as normal compression refrigerators but involve low voltage DC compressors and motors (12V or 24V). Normally, the batteries can store solar energy for 5 days. It is important to clean the solar panel on a periodic basis for removing dirt, soot, smog and debris, as shading of as less as 10% of panel area with dirt or bird droppings can reduce power output by 50% (similar to that of a cloudy day).

**Automatic voltage stabilizer** This is an important part of cold chain system, which corrects the fluctuations in the main voltage and maintains it in range of 220 ± 10 V, which is necessary for ensuring correct storage temperature. Each electrical refrigeration equipment should necessarily be connected to a separate dedicated mains supply via a separate functional stabilizer at all levels of the cold chain. Different types of voltage stabilizers used in cold chain system are as follows: *servo-mechanical voltage stabilizers* recommended for areas with mains voltage range variation up to 50%; *electronic voltage stabilizers* for equipment requiring extremely fast correction speed and those located in hostile climatic conditions; and *tap changing voltage stabilizers* recommended for less sensitive equipment.

### Nonelectrical Cold Chain Equipment

**Cold boxes** These are big insulated boxes mainly used for transportation of vaccines (and diluents) and also for storing vaccines in case of power failure or equipment breakdown. These are available in different sizes such as 5, 8, 20 and 22 liters depending on the storage capacity and are supplied with requisite number of water-packs. A 5 and 8 liter cold box can store 1,500 and 2,400 doses of mixed antigens respectively. Vaccines are placed in cartons or polythene bags inside the cold box and while arranging vaccines either for storage or transportation it is essential to ensure that OPV and single antigen lyophilized vaccines (those packed with frozen water-packs) are placed separately from freeze sensitive and multivalent vaccines (those packed with cool water-packs). After placing vaccines, frozen/cool water-packs are arranged over top of vaccines and diluents and covered with plastic sheet for ensuring full hold over time. Freeze indicator should also be placed inside cold box to monitor that the storage temperature has not dropped below 0°C. In order to maintain proper functioning of cold boxes, it is essential that after every use they are examined both internally and externally for any cracks, rubber seal around the lid is checked, hinges and locks are lubricated periodically and are kept unlocked and opened while not in use.

**Vaccine carriers** These are insulated boxes used to carry small quantities of vaccines and diluents (approximately 16–20 vials) to immunizations sessions in the outreach areas. These are supplied with four water-packs and a foam pad to cover vaccines from top and maintain the storage temperature. Vaccine carriers should be packed with mix of vaccines and diluents with cool water-packs in order to prevent damage to freeze sensitive vaccines. The diluents (and droppers as for OPV) should be packed with vaccines for

transportation to outreach sites, taking care that diluents does not come in direct contact with the frozen/conditioned water-packs. Vaccine carriers should be wiped and cleaned dry both from inside and outside each time after use and stored with lid opened.

**Water-pack (Ice-pack)** These are flat plastic containers, filled with fixed quantity of water (0.3 L, 0.4 L and 0.6 L depending on size and manufacturer) and are prepared as *frozen water-pack* (for storage and transportation of OPV and single antigen freeze dried lyophilized vaccines), *cool water-pack* (for transportation of liquid vaccines other than OPV) or a *warm water-pack* (stabilized at room temperature between +10°C and +24°C and used for transportation of freeze-sensitive vaccines for a period up to 8 hours). The water-packs frozen inside deep freezer have a surface temperature of -15°C to -25°C, which can cause freeze damage particularly to freeze-sensitive vaccines during transportation. Therefore, before packing frozen water-packs, they are kept in open at room temperature until the ice within it which is in contact with the walls melts. This process is known as conditioning of water-packs and the time required for melting some ice depends on the ambient temperature and can take up to 30 minutes.

## MONITORING OF COLD CHAIN

Monitoring of cold chain is an indispensable part of entire cold chain system and it helps to ensure that adequate number of type of cold chain equipment are available and functioning, vaccine supply is timely and adequate, storage temperatures and other conditions are as recommended and that all vaccines are potent and safe to use.

### Temperature Monitoring Devices

**Fixed dial thermometer** These are used to measure temperature inside ILR and DF and can show the temperature in the range of -50°C to +50°C. Bimetallic dial thermometers are no longer used because they easily lose their calibration.

**Alcoholic stem thermometer** These thermometers are more sensitive and accurate than dial thermometers and can record the same temperature range. These can be used in all types of refrigerators and freezers; however, since they do not provide a continuous record of vaccine temperature exposure therefore they should not be used as primary temperature monitoring device.

**Electronic data logger** This is an electronic device which is placed within the vaccine vials and record temperature for a period of 30 days. This is equipped with alarm system which alerts the handlers whenever the storage temperature crosses the safe range. These are specifically designed to be used in ILRs and WICs which are required to maintain the temperature between +2° and +8°C.

### Vaccine Management: Storage and Distribution

It is necessary to ensure that at any point of time, sub-district level cold chain facility has adequate quantity of vaccines estimated as per requirement for the catchment area for a particular period of time. In addition to monthly requirement, a designated buffer stock of each vaccine (25% of monthly requirement) should also be available to meet extra demand or any delay in supply. Estimate of requirements for each different vaccine should be done for the catchment area on periodic basis and the quantity of any particular vaccine should be requested/indented depending on the number of beneficiaries in the area, number of doses required for a vaccine by one beneficiary to complete immunization schedule and the wastage factor for that vaccine. General guidelines for storage of vaccines are as follows:

- All vaccines stored in ILR should be placed in baskets (supplied with equipment) in separate labeled boxes for easy identification and with adequate space between them for air

circulation (2 cm space on all sides and between boxes). The boxes should also have holes to facilitate good access to cool air.

- In case basket is not available vaccine boxes should be kept over two layers of empty water-packs placed to prevent direct contact with the floor (also prevents boxes to get wet by water collected at bottom).
- Every cold chain equipment should have one thermometer placed in basket with vaccines or between the vaccine boxes for twice daily monitoring of storage temperature. Care should be taken that thermometer is placed in contact with the walls.
- Freeze sensitive vaccines and those with close expiry should be kept on top in ILR basket (and front in front opening refrigerators) so that they are utilized first.
- Diluents should not be frozen or stored inside deep freezer as these ampoules are not designed for freezer storage and can crack.
- Food items, drinks, other drugs and vaccines not included in national immunization program should not be stored in equipment (electrical or nonelectrical) in which vaccines are stored.
- Cold chain equipment should be plugged directly into the wall outlets, with a label *Do not unplug*. Alternatively, plug guards or safety-lock plugs can be used to prevent inadvertent unplugging of the equipment.
- Every equipment should be defrosted and cleaned at least once every month or when the frost on inner walls is more than 0.5 mm. At time of defrosting vaccines should be shifted to other equipment or in cold boxes with adequate number of cool water-packs.
- Proper record keeping is crucial for ensuring quality cold chain system and separate date-wise records of vaccine receipts, distribution and balance sheets should be available for each type of vaccine and vaccine product. Other information to be recorded and updated include the date of receipt, name of manufacturer, batch number, manufacture and expiry date, VVM status and any other information available for ensuring the quality and potency of vaccines and vaccine products.

**Vaccine inventory control** For ensuring adequate and effective immunization coverage in an area, it is important that availability of vaccine stock is ensured at all times. A vaccine inventory should be conducted on monthly basis to ensure adequate supply for meeting demand. Diluents are also a part of inventory and it is essential that they are available in adequate supply. Factor which determine the requirement of vaccines and diluents are projected demand, storage capacity, and current vaccine supply.

Problems generally encountered with respect to stock position include—inadequate stock (amount available is less than the buffer stock, i.e. 25% of monthly requirement), stock out (when a particular vaccine or vaccine product is not available) and excess stock (when available stock is more than 1 month requirement and buffer stock, i.e. more than 125%), which leads to vaccine wastage or outdated vaccines in hand.

## GUIDELINES FOR USE OF OPENED MULTIDOSE VIALS

Earlier it was generally followed that all vaccine vials opened for an immunization session were discarded at the end of session, irrespective of the type of vaccine or the remaining number of doses. However, for vaccines including OPV, DTP, TT, DT, Hepatitis B and liquid Hib revised policy has been instituted by WHO provided that these vaccines meet WHO requirements for potency and temperature stability, are packaged according to ISO standards and contain and appropriate concentration of preservative (e.g.

thiomersal for injectable vaccines only). For these vaccines revised policy states that:

Multidose vials of OPV, DTP, TT, DT, Hepatitis B and liquid formulations of Hib vaccines from which one or more doses of vaccines have been removed during an immunization session may be used in subsequent immunization sessions for up to a maximum of 4 weeks, only when the following conditions are met:

- The expiry date has not passed
- The vaccines are stored under appropriate cold chain conditions
- The vaccine vial septum has not been submerged in water
- Aseptic technique has been used to withdraw all doses
- VVM (if attached) has not reached the discard point.

The revised policy does not change recommended procedures for handling vaccines that require reconstitution, i.e. BCG, measles, yellow fever and some formulations of Hib vaccine. These vaccines once reconstituted, vials must be discarded at the end of immunization session or at the end of recommended period of use whichever comes first. As per WHO guidelines, reconstituted vaccines should not be used beyond 6 hours of time of reconstitution. In India's Universal Immunization Programme, BCG, measles and Japanese encephalitis (JE) are the vaccines which require reconstitution, out of these reconstituted BCG and measles are not to be used beyond 4 hours and Japanese encephalitis (JE) vaccine not beyond 2 hours from the time of their reconstitution.

**Vaccine disposal** There are situations when the vaccine vials and other vaccine products need to be terminally disposed and there are specific guidelines for disposal of unopened unexpired vials, expired vials, opened vials with unused doses, doses drawn but not administered and potentially compromised vaccines resulting due to inappropriate storage conditions. To dispose vaccines in these different forms medical waste disposal procedures outlined in national level policies and guidelines must be followed.

### IN A NUTSHELL

1. Effective cold chain network is most essential to ensure quality immunization services.
2. Temperature ranging from +2°C to 8°C is generally safe for storage of nearly all the vaccines.
3. Sunlight and fluorescent (neon light) can also cause loss of potency of the vaccines.
4. A wide range of equipment is available for the cold chain system having different capacities and features to suit different local conditions and needs.
5. It is important to monitor the expiry date and VVM (where applicable) before distributing, opening or using these vaccines.
6. All vaccines stored in the cold chain equipment should have separate labeled boxes for easy identification and adequate space between them for air circulation.
7. Proper record-keeping is crucial for ensuring quality cold chain system.

## Chapter 23.5

## Adverse Events Following Immunization

Ajay Kalra

An adverse event following immunization (AEFI) is defined as medical incident that takes place after immunization, causes concern, and is believed to be caused by immunization. The event can be a true adverse event or an event coincidental to the immunization. AEFIs are classified into the categories given in **Table 1**.

## VACCINE REACTIONS

The vaccine can cause adverse events due to its inherent properties. They are usually of two types: (a) Minor reactions and (b) Serious reactions. Most vaccine reactions are minor and settle down on their own.

*Minor reactions* are more common. They can be local like pain swelling and/or redness at injection site or systemic such as fever, vomiting, malaise which can result from the normal immune response to the vaccine.

*Serious reactions* are rare. They can be in the form of seizures, encephalopathies [as in pertussis and measles, mumps, and rubella (MMR) vaccines], hypotonic, hyporesponsive episode (pertussis) severe allergic reactions (all vaccines) anaphylaxis (all vaccines), suppurative lymphadenitis, osteitis, disseminated infection [all with *Bacillus Calmette–Guérin* (BCG) vaccine], brachial neuritis, thrombocytopenia.

## PROGRAMMATIC ERRORS

Program errors result from errors and accidents in vaccine preparation, handling, or administration (**Table 2**). Programmatic errors are the most common causes of serious adverse events and deaths following vaccination. The identification and correction of these errors are of great importance as they are preventable and detract from the overall benefit of the immunization program. The most common program error is an infection as a result of nonsterile injection. The infection can manifest as a local reaction (e.g. suppuration, abscess), systemic effect (e.g. sepsis or toxic shock syndrome), or blood-borne virus infection [e.g. human immunodeficiency virus (HIV), hepatitis B or hepatitis C].

A program error may often be suggested by a cluster of events associated with immunization. A cluster of AEFIs is defined as two or more cases of the same adverse event related in time, place or vaccine administered. These clusters are usually associated with a particular provider, or health facility, or even a single vial of vaccine that has been inappropriately prepared or contaminated.

## INJECTION REACTION

This event is from anxiety about or pain from the injection itself rather than the vaccine. Syncope due to pain of injection in an adolescent girl is the best example of this category.

*Coincidental* The event that happens after immunization but not related to it, is a chance association. Sudden infant death syndrome following vaccination is known event which is coincidental.

*Unknown* The event for which cause cannot be determined.

Besides the above-defined reactions, there are situations which are vaccine scare related due to theories of a causal link which are not actually established. These vaccine scare-related adverse events have no established causal link and are most often

**Table 1** Classification of adverse events following immunization (AEFI)

Type of AEFI	Definition	Example
Vaccine reaction	An event caused or precipitated by the active component or one of the components of the vaccine	Anaphylaxis due to measles vaccine
Program error	An event caused by an error in vaccine preparation, handling or administration	Bacterial abscess due to unsterile injection
Injection reaction	Event from anxiety about, or pain from the injection itself rather than the vaccine	Syncopal attack in a teenager after immunization
Coincidental	An event that occurs after immunization but is not caused by the vaccine. This is due to a chance association	Acute gastroenteritis 5 days after DPT immunization
Unknown	Events cause cannot be determined	

**Table 2** Programmatic errors leading to adverse events following immunization (AEFI)

<i>Nonsterile Injection</i>	
<ul style="list-style-type: none"> <li>Reuse of disposable syringes or needles</li> <li>Improperly sterilized syringes or needles</li> <li>Contaminated vaccines or diluents</li> <li>Reuse of reconstituted vaccine at subsequent session</li> </ul>	<ul style="list-style-type: none"> <li>Local suppuration at injection site, abscess, cellulitis</li> <li>Systemic infection</li> <li>Sepsis</li> <li>Toxic shock syndrome</li> <li>Transmission of blood-borne infections such as HIV, Hepatitis B, Hepatitis C, malaria, etc.</li> </ul>
<i>Vaccine administered at improper site</i>	
<ul style="list-style-type: none"> <li>SC instead of ID BCG</li> <li>Hepatitis B and Anti-Rabies vaccine given on gluteal region</li> <li>DPT such as vaccine not given by deep IM route</li> </ul>	<ul style="list-style-type: none"> <li>BCG adenitis</li> <li>Ineffective vaccine or poor immunologic response</li> <li>Local reactions such as induration, nodule formation</li> </ul>
<i>Incorrectly prepared vaccine</i>	
<ul style="list-style-type: none"> <li>Vaccine reconstituted with incorrect diluent</li> <li>Drugs substituted for vaccine or diluent</li> <li>Storage and transportation of the vaccine incorrectly</li> <li>Contraindication ignored</li> <li>Avoidable vaccine reactions</li> </ul>	<ul style="list-style-type: none"> <li>Local reaction or abscess formation</li> <li>Effect of drug used such as insulin, muscle relaxant</li> <li>Ineffectiveness of the vaccine</li> <li>Increased local reactions from frozen vaccines</li> </ul>

hypothetical. An example of this is MMR and autistic spectrum disorder or inflammatory bowel disease. Review of all currently available evidences does not support any casual relationship between MMR vaccine and autism or inflammatory bowel disease. Thiomersal (50% ethyl mercury), a preservative in inactivated vaccines particularly in multidose vials, has been linked in the past to autistic spectrum disorders and neurodevelopmental disorders. Consequently, most of the vaccine preparations available in the developed nations are thiomersal free. Systemic review of evidences, however, has not supported any casual association between thiomersal and neurotoxic effects. Therefore, in developing nations, where multidose vials significantly bring down vaccine costs and cold chain space requirement, the benefits of thiomersal far outweigh any possible risks. Asthma, sudden infant death syndrome, chronic fatigue syndrome, immune deficiency, leukemia, autoimmune diseases, learning disorders, etc., are other diseases of unknown or only partially understood etiology which are also linked with vaccines.

AEFIs due to individual vaccines are listed in **Box 1**.

## MANAGEMENT OF COMMON AEFI

A summary of management guidelines of some commonly encountered AEFI are outlined in **Table 3**.

### Anaphylaxis

Severe allergy or anaphylaxis occur rarely following vaccination, with a frequency of 1 per 1,000,000 vaccine doses. They may present as generalized urticaria, hives, wheezing, swelling of mouth and throat, difficulty in breathing, hypotension and shock. As occurrence of anaphylaxis cannot be predicted, all those who have received a vaccine should be observed for at least 15 minutes postvaccination. There should be availability of all resuscitative equipment and emergency drugs at the place of vaccination.

- Place child in recumbent position and elevate feet
- Clear airway, establish breathing (oxygen, bag and mask) and maintain circulation

#### BOX 1 Adverse effects following specific vaccines

##### *Bacillus Calmette-Guérin (BCG) vaccine*

Persistent discharging sinus at the site of vaccination, secondary infection at the vaccination site, BCG adenitis and cold abscess formation, disseminated BCG infection (especially in immunocompromised children), osteitis, tuberculous osteomyelitis

##### *Diphtheria-Pertussis-Tetanus (DPT) vaccine*

Local pain, erythema and induration at injection site, fever, persistent inconsolable crying (> 3 hours), febrile convulsions, hypotonic hyporesponsive episode (HHE), anaphylactic reaction, encephalopathy

##### *Oral Polio Vaccine (OPV)*

Almost none, rarely vaccine associated polio paralysis (VAPP)

##### *Inactivated Poliovirus vaccine (IPV)*

Local pain, erythema, induration at injection site, hypersensitivity to streptomycin or neomycin (used as preservatives)

##### *Measles vaccine*

Mild fever, coryza, rash, dissemination of tuberculosis (especially in immunocompromised children), encephalitis, toxic shock syndrome (TSS) due to contamination of measles vaccine by *S. aureus*, thrombocytopenia. Rarely subacute sclerosing pan encephalitis (SSPE)

##### *Measles, Mumps and Rubella (MMR) vaccine*

Mild fever, rash, encephalopathy, parotid swelling, aseptic meningitis, Guillain-Barré syndrome (due to mumps component), arthralgia, lymphadenopathy (due to rubella component)

##### *Hepatitis B vaccine*

Soreness at the site of injection, mild fever, myalgia, arthralgia, rarely anaphylaxis

##### *Hepatitis A vaccine*

Soreness, induration at injection site, headache, nausea, loss of appetite

##### *Typhoid vaccine (Vi antigen vaccine)*

Pain and induration at injection site, fever

##### *Tetanus toxoid (TT)*

Repeated TT injections after trial injuries can lead to reduced immunogenicity, hypersensitivity, hemolytic anemia, etc.

##### *Haemophilus influenzae type b (Hib) vaccine*

Local pain, redness and swelling at injection site

##### *Varicella vaccine*

Local reactions such as pain, redness and swelling at vaccination site, fever systemic varicella such as rash in around 5%, herpes zoster

##### *Human papillomavirus (HPV) vaccines*

Pain, erythema and swelling at the site of vaccination, fever. No deaths have been reported casually associated with HPV vaccines

##### *Pneumococcal vaccine*

Pain, erythema and swelling at injection site, fever

##### *Rotavirus vaccine*

No increased risk of intussusception

##### *Rabies vaccines*

Pain, redness and swelling at vaccination site, fever, headache, dizziness and gastrointestinal side effects. Systemic hypersensitivity reactions have been reported with human diploid culture vaccine (HDCV)

##### *Influenza vaccines*

Fever, rash. No extra risk of Guillain-Barré syndrom (GBS)

##### *Yellow fever vaccine*

Encephalitis, ADEM, GBS, yellow fever mimicking illness (may be fatal).

**Table 3** Management guidelines of common AEFI at health facility

No.	Adverse events	Vaccine	Symptoms	Management
1.	Anaphylaxis	Any vaccine	Within minutes 1. Acute decompensation of circulatory system 2. Hypovolemic shock 3. Laryngospasm/edema 4. Acute respiratory distress	1. Adrenaline 2. Cardiopulmonary resuscitation 3. IV volume expanders 4. Hydrocortisone 5. Dopamine/Dobutamine
2.	Hypotensive-hyporesponsive episode (HHE)	DTP	1. Acute paleness 2. Transient decreased level or loss of consciousness 3. Decrease or loss of muscle tone	1. IV fluids 2. Oxygen
3.	Inconsolable cry	DTP	1. Within 48–72 hours of Immunization 2. Excessive inconsolable crying	1. Sedation with Triclofos-50 mg/kg 2. Paracetamol (10–15 mg/kg/per dose) 3. Feeding advice
4.	Toxic shock syndrome	Contamination of Measles vaccine by <i>S. aureus</i>	1. Within 30 minutes to few hours 2. Mounting fever 3. Vomiting 4. Diarrhea 5. Septic shock	1. IV fluids 2. Antimicrobials cloxacillin 50–100 mg/kg/day 3. Steroids 4. Supportive therapy
5.	Lymphadenitis	BCG	Within 2–6 months Firm to soft axillary lymphadenitis 1.5–3 cm size	1. If firm, no treatment 2. If soft and fluctuant, aspiration/surgical excision 3. Anti-tubercular therapy not indicated
6.	Seizure(s) with fever (rare)	DTP, measles	Always generalized	1. Anticonvulsants 2. IV fluids (if need be)
7.	Bacterial abscess	Any vaccine	After days to weeks fluctuant or firm	1. Antibiotics 2. Antipyretics 3. Drainage
8.	Moderate-to-severe local reaction	Any vaccine	Nonfluctuant swelling/redness 3–10 cm size at the injection site	1. Paracetamol

Source: Adapted from Science of Vaccinology Module, Indian Academy of Pediatrics, 2012.

- Administer epinephrine (1:1,000 solutions) in the dose of 0.01 mL/kg (max 0.5 mL) IM/SC, may be repeated every 3–5 minutes, if required
- If child is hypotensive, setup IV access and give volume expanders. Normal saline or ringer lactate 20 mL/kg over 10–15 minutes. Two to three boluses can be repeated to get response, if required.
- Injection hydrocortisone (IM or slow IV) in the dose of 25 mg in children less than 6 months, 50 mg in 6 months to 6 years, 100 mg in 6–12 years and 200 mg in above 12 years age.
- Oral antihistaminics may be given to ameliorate skin symptoms. Intravenous antihistaminics are not recommended
- Monitoring of vitals is essential.

## PREVENTION OF AEFI

It is mandatory for the person administering the vaccine to have sufficient knowledge regarding the vaccines, proper technique of administering the vaccine and expected adverse events. Parents should be explained in detail regarding vaccine and its possible adverse effects. The equipment for resuscitation in a case of severe AEFI like anaphylaxis should be kept available at the place of vaccination. The functioning of the equipment should be confirmed. The vaccines should be kept at the recommended temperature and cold chain should be maintained. Vaccines must only be reconstituted with the diluent supplied by the manufacturer. Reconstituted vaccines must be discarded at the

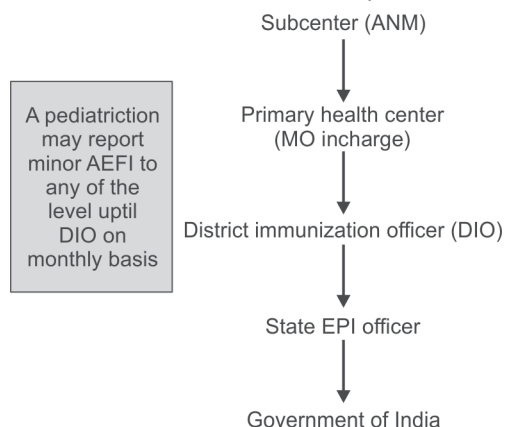

end of each immunization session and should never be retained. No other drugs or substances should be stored in the refrigerator of the immunization center.

## REPORTING OF AEFI

Reporting should be done as quickly as possible so that an immediate decision on the need for action and investigation can be made. This is called the first information report (FIR). Private practitioners should also report events that come to their notice. The minor AEFIs should be reported every month to the subcenter or the primary health center (PHC) or the district immunization officer (DIO) who sends reports to the state EPI officer. Eventually, the report reaches the Central Government (**Flow chart 1**). The serious AEFIs should be referred without any loss of time especially within 24 hours. In these cases, the FIR can be sent to the PHC, community health center (CHC) or the district health authorities. The district authorities forward these reports within 24 hours to the state and central health authorities. The report should contain the description of the event, timing of the event in relation to immunization, vaccines given, batch number and other details of the vaccine, identifying details of the patient, etc. The peripheral health worker or supervisor in the periphery should report all AEFIs to the higher center or the district authority. The medical officer (MO) at the PHC or the DIO should conduct a preliminary investigation and send the report (PIR) to the state and central health agencies within 7 days. A detailed report is to be sent by AEFI

**Flow chart 1** Routine monthly reporting of 'Minor' AEFI cases (How, Whom and When to report)

investigation team within 90 days. **Table 4** provides a summary of the formats and timelines of reporting serious AEFI cases. The vaccination program should be continued while awaiting the completion of the reporting and investigation. The media play an important role in public perception. Key messages should be prepared before the media contact.

**Table 4** Reporting of serious AEFI cases (formats and timelines)

Type of report	Responsible	Timeline
<i>FIR</i> First Information Report	Pediatrician/Private Practitioner/MO	48 hours
<i>PIR</i> Preliminary Investigation Report	MO/DIO	7 days
<i>DIR</i> Detailed Investigation Report	AEFI investigation team	90 days

## IN A NUTSHELL

1. Most adverse events are minor and self-limiting and can be easily managed.
2. Proper management, reporting and investigation of the significant (albeit rare) adverse events are important to prevent recurrences.
3. With universal vaccine usage, risks and adverse effects receive much higher priority from the public and needs to be addressed so as to not offset the benefits of universal immunization.

## Chapter 23.6

# BCG Vaccine

Sangeeta Sharma

Bacille Calmette-Guérin (BCG) is the deliberate administration of a suspension of live attenuated *Mycobacteria bovis*-Calmette and Guérin strain to produce immunity against tuberculosis (TB). In 1908, Edmond Nocard first isolated a strain of *Mycobacteria bovis* from a cow with tuberculous mastitis, known as Lait Nocard strain. Over a span of 13 years, until 1921, Calmette and Guérin performed successive 231 subcultures to the attenuate these bacilli, to produce the BCG strain. This strain was later lyophilized at the Pasteur Institute and distributed to various countries. Different ways of sequential culture performed in different countries led to the origin of different substrains due to eight genetic mutations over a 40-year period. The substrain brought by Julio Elvio Moreau to Uruguay in 1925, known as *Moreau strain*, had already undergone two mutations while the BCG vaccine brought by Arlindo de Assis to Brazil in 1927 was actually a daughter strain of the *Moreau strain*, the BCG vaccine brought by Moreau. This was therefore named as BCG *Moreau-Rio de Janeiro, Brazilian strain*, the most immunogenic strain known. World Health Organization (WHO) has recognized 12 vaccine substrain preparations till now, which are currently available.

Presently, BCG vaccine is being produced by several laboratories around the world. Although the preparations are made from attenuated *M. bovis*, they are not identical due to the different genotypic and phenotypic characteristics of the substrains. As a result, depending on the substrain, they have different viability, immunogenicity, reactogenicity, residual virulence, potency and efficacy. The number of particles cultivated per dose is also different, e.g., varies from 37,500 to 500,000 in the Pasteur substrain and from between 200,000 and 3,200,000 in the Copenhagen substrain. Recent genomic studies have shown that different BCG vaccine substrains differ in the genetic code.

BCG vaccine was extensively used in Europe between 1920 and 1930 as an oral BCG vaccine. In 1929 in Lubek, Germany, an oral BCG vaccine lot caused 72 deaths among 251 children vaccinated. Although it was later found to be due to an unintentional contamination of the vaccine with a virulent TB strain, this led to a big question mark on the routine immunization practices with BCG. Intradermal BCG vaccination and multiple puncture technique were introduced in 1927 and 1939, respectively. Currently, BCG vaccination covers 85% of newborn infants all over the world. Developing countries of Africa, Southeast Asia and the Western Pacific have lower vaccination rates.

## TYPES OF BCG VACCINE

### Liquid Vaccine

It loses potency very quickly with rapid deterioration occurring within 2 weeks if exposed to light or temperature fluctuation.

### Freeze Dried Vaccine

The solution harvesting the bacilli is frozen. It can be stored at room temperature (with 1% sodium glutamate as preservative). It remains viable for 12 months.

## TECHNIQUES OF ADMINISTRATION

### Intradermal Technique

It is the most common technique with 0.1 mL of BCG vaccine injected into the left arm at deltoid insertion, leading to a wheal formation of 5–7 mm, which later transforms into a papule in

1 week and ulcerates at 3–4 weeks, finally healing by scar formation in 3 months.

### Oral Vaccine

BCG was introduced for the first time as an oral vaccine in France. There are many disadvantages of this technique like large dose requirement, and sensitivity to temperature. Cervical adenitis is also more common.

### Multiple Puncture Technique

The vaccine is given intradermally using multiple punctures. It is not suitable for mass immunization as it requires a large dose.

### Jet Injections

The vaccine is given intradermally using jet syringe and needle but it is also not suitable for mass immunization.

## PROTECTIVE EFFICACY

In several case-control studies and clinical trials conducted worldwide reported the protective efficacy rate of BCG range between 0 and 80% depending on the geographic area and the study design. Protection against tuberculous meningitis and miliary tuberculosis was consistently higher (> 50%) in all these studies. The wide variation in the protection levels so obtained could be attributed to the differences in some aspects of these studies, for instance, the age of the cases included in the analysis, proportion of different clinical forms of TB, source of controls, selection criteria for controls and sample size, etc., which may influence the results so obtained. The largest clinical trial carried out by the Indian Council of Medical Research (ICMR) in Chingleput, Chennai showed no protection against TB.

Three meta-analyses conducted by Rodrigues et al. (1993), and Colditz et al. (1994, 1995) have analyzed the studies on BCG vaccine for preventing TB. The results were homogeneous for the protective efficacy of BCG vaccine against tuberculous meningitis and miliary TB, ranging between 72% and 100%, with a summary estimate of 86%. Summary estimates of the protection afforded by BCG vaccine against all forms of TB were similar for randomized clinical trials (RCT) and case-control studies (51% and 50%, respectively). Nevertheless, the protective efficacy of BCG vaccine against pulmonary TB was quite heterogeneous, as several RCTs revealed rates ranging between 8% and 79%. A recent study from Turkey carried out on children exposed to domestic contact with TB cases using the enzyme-linked immunospot (ELISpot) test suggested a protective effect of 40% against the primary infection. The BCG vaccine can also prevent the infection from becoming an active illness.

## Reasons for Heterogeneity

Many factors have been implicated for the heterogeneity in the protective efficacy of BCG, especially with regard to pulmonary TB:

- Biological variability of BCG vaccine of different strains and stability of vaccine.
- Studies using the same BCG strain in different countries report different levels of protection due to frequent exposure to environmental mycobacteria (EM) which may influence the recipient's *BCG take*, thus interfering with the efficacy of BCG vaccine. Clinical trials carried out with populations from countries located far away from the equator, with low or no prevalence of EM, had high efficacy rates (greater than 70%), while in a study conducted in southern India the low protective efficacy observed is consistent with exposure to EM. A meta-analysis revealed that 41% of the discrepancy in the estimated efficacy is due to latitude, which may represent exposure to EM.

- **Route of infection:** The vaccine protects against progression of primary complex (e.g., meningitis and disseminated TB), while there is a low protective efficacy against reinfection. If this hypothesis were true, there would be low protective efficacy in those populations at high-risk for infection and reinfection.
- Differences in the virulence of the *M. tuberculosis*, high-risk of reinfection; viability, dose and route of vaccine administration also play a role.
- Host-related factors like nutritional status, other coexisting infections and genetic make-up also influence the protective response to the vaccine.

## DURATION OF PROTECTION

The length of the protective efficacy of BCG vaccine plays an important role in the establishment of vaccination policies. According to the literature, the protection provided by BCG vaccine decreases with time, i.e., 10–15 years. In Great Britain, the Medical Research Council conducted a study between 1950 and 1970, including 54,239 participants aged 14 and 15 years to assess the length of protective efficacy of BCG vaccine. The analysis carried out every 5 years revealed that protection decreased from 84% in the first 5 years to 59% between 10 years and 15 years, showing a reduction in protective efficacy. A study based on a placebo-controlled clinical trial including American Indians and Alaska Natives has been recently published revealed a decline in efficacy at the beginning of the follow-up period (1935–1947) from 77% to 52% during a six-decade follow-up (period from 1948 to 1998). A study of the RCT control group on the efficacy of the second dose of BCG vaccine in Brazilian school-aged children demonstrated that the protective efficacy of neonatal BCG against all forms of TB lasts for 15–20 years.

## BCG REVACCINATION

### Protection

Revaccination was given to children and adolescents in Hungary from 1959, when high incidences of TB were found, with levels comparable to a serious epidemic. Revaccination was administered to tuberculin-negative children and adolescents with the second dose of the BCG vaccine. It was found to provide no protection. These results acted in support of the decision to suspend the Brazilian revaccination program against TB.

### Repeated Vaccination

Russia, Portugal, Chile and Hungary, use repeated doses of BCG vaccine against pulmonary TB, on the assumption that the protection provided by the vaccine decreases with time. Most of the evidence regarding the second dose of BCG vaccine is based on observational studies. After the second dose of BCG vaccine was discontinued in purified protein derivative (PPD)-nonreactive children, the number of cases did not increase, compared to the cohort of children revaccinated with BCG vaccine. The WHO recommends the use of one dose of BCG vaccine against TB, given the lack of evidence supporting the use of additional doses.

In some of these countries, the use of BCG vaccine has been discontinued in order to safeguard the diagnostic value of PPD as an indicator of previous MTB infection. Countries with a low incidence of TB like USA, United Kingdom have focused on the identification and treatment of infected individuals in order to prevent transmission of disease and occurrence of new cases. In other countries, such as Brazil, revaccination has recently been discontinued and BCG vaccine is now given at birth only. Other control measures include early diagnosis, treatment of TB cases, and chemoprophylaxis of contacts.

## ADVERSE EVENTS

BCG vaccine is a fairly safe vaccine. Adverse events resulting from the vaccination are infrequent with local adverse events like accelerated ulceration, axillary lymphadenopathy occurring in 0.01–6.0 per 1,000 livebirths. Adverse events that involve the generalized spread of the BCG vaccine infection usually 6–12 months after receipt of the vaccine are rare but can occur in immunocompromised children.

## CONTRAINDICATIONS

- Dermatological infection in the area where the vaccine is to be administered
- Children on immunosuppressant drugs
- Congenital immunodeficiency
- Children with acquired immune deficiency syndrome (AIDS).

## BCG VACCINE IN HIV-POSITIVE CASES

Case-control studies performed in human immunodeficiency virus (HIV) positive children did not provide any evidence of the protective efficacy of BCG vaccine against pulmonary and extrapulmonary TB. The use of live attenuated vaccines may pose risks to HIV-positive individuals. In 1987, the WHO concluded that the benefits of providing the BCG vaccine to all children in high incidence countries are greater than the risks of adverse events occurring among HIV-positive groups. In these countries, vaccination is recommended for HIV-positive children except those with AIDS. Countries with low prevalence of TB do not give BCG vaccine to these groups. In 2004, the recommendation was revised to include the proposal that vaccinated children to HIV-positive mothers, should be monitored to for the occurrence of possible adverse events like localized reaction, occurrence of lymphadenitis, or the spread of the BCG infection.

## STRATEGIES FOR BCG VACCINATION AROUND THE WORLD

### First Dose of BCG Vaccination

As per WHO recommendations, most national immunization programs of various countries recommend a single dose of BCG for all newborn babies. In high endemic regions, additional doses have mainly been adopted in order to protect against the spread of very serious forms of the infection especially in young children and adolescents, though there is lack of evidence of its extra efficacy.

BCG vaccine is not recommended for newborn babies in seven European countries namely Luxembourg, Andorra, Austria, Germany, Spain, Belgium and Denmark. In the last two countries of this group, the vaccine is only recommended for children who move from high incidence countries. East European countries give the BCG vaccine to newborn babies. France, Norway, United Kingdom, Malta, Greece, Holland and Slovenia vaccinate children when they are adolescents, i.e., 12–13 years old. Low incidence countries like USA, Sweden and Canada vaccinate only high-risk groups such as health professionals working in endemic areas, children who have been exposed to multi-resistant TB and homeless people.

### Second Dose of BCG Vaccination

Hungary and Russia administer multiple doses of BCG, on the basis that the protection diminishes over time. In Thailand and Japan, school children who do not develop a scar receive a second vaccine, while in Turkey, a second dose is recommended for school children, irrespective of scarring or PPD. In Slovakia, the Czech Republic, Poland and Bulgaria, school children are revaccinated

when the result of their PPD test is negative. Brazil has recently suspended the use of the second dose of the BCG vaccine in school children due to lack of evidence of its efficacy.

## NEWER TUBERCULOSIS VACCINES

The current BCG vaccine is not very effective in preventing pulmonary TB, the most common and most infectious form of the disease. Efficient drug therapy exists, but the treatment is long and case detection rates are low, making the development of a better vaccine an important goal. Cochrane database analyses have shown that BCG vaccine being used today can only protect against development of severe and disseminated forms of tuberculosis amongst children, i.e., tubercular meningitis and miliary tuberculosis and is not very effective at preventing primary complex. Also, the conventional BCG does not boost the immune response to a level that it can prevent reactivation/reinfection TB. Therefore, revaccination with a second dose of BCG is fast losing ground due to loss of efficacy.

An ideal TB vaccine should therefore not only prevent the progression of primary TB disease but should also be able to prevent the primary infection, its transmission and reactivation, should be safe, should not interfere with the diagnosis and if required also be used as an adjunct to chemotherapy. Therefore, it should work either before or after primary infection but with a long standing, preferably lifelong immunity, without need for frequent boosters. It should also have a low cost.

## Difficulties in Development of the Newer BCG Vaccine

Animal studies/models provide limited information as these cannot be extrapolated on potential human vaccine candidates due to lack of good *protective markers*. Moreover, most human beings have either already been immunized with BCG or exposed to atypical

environmental mycobacteria. Therefore, it may not be possible to find a clean catch human population for the trial of a new vaccine. Also, as the level of immunity cannot be increased any further in these already immunized or environmental mycobacteria exposed individuals, the new vaccine might not seem to give the expected results in these cases. Induction of a strong immune response in some infected persons may produce immunopathology. The newer vaccines are shown in **Table 1**.

Deoxyribonucleic acid (DNA) subunit vaccines (recombinant, natural, synthetic), virus vector vaccines or recombinant protein vaccines are capable of carrying one or more immunodominant antigens of the *M. tuberculosis*. These may possibly be used to substitute the BCG vaccine and include:

- MVA85A (recombinant modified vaccinia Ankara expressing antigen 85A) is recombinant virus vector vaccine (attenuated vaccinia virus) expressing antigen 85 A in the *M. tuberculosis*. This is considered to be safe and displayed good results in a population of noninfected and also previously BCG received guinea-pigs. In 2003, phase 2 of the study began in South Africa.
- rBCG30—recombinant vaccine (antigen 85 B).
- Mtb72F—recombinant vaccine that includes polyproteins, obtained by combining two antigens (Mtb32 and Mtb39) that are recognized by the immune system of the infected patient. In 2004, phase 1 of studies began in the United States.
- ESAT6 and Ag85B—recombinant vaccines that express polyproteins. In 2005, phase 1 of studies began in Europe.

## Current Status of New BCG Vaccines

Results of the phase I trial of a leading new TB vaccine MVA85A have shown it to be an effective, safe, and immunogenic in the BCG-vaccinated individuals without any induction of immunopathology. This is the first subunit TB vaccine to enter clinical trials in *M. tuberculosis*-infected subjects.

**Table 1** Selected promising tuberculosis (TB) vaccines

Vaccine candidate	Example	Comment	Current status	Reference
<i>Subunit vaccine</i>				
Antigen and Adjuvant	Mtb 72 F	Skewed Ag profile	Ph I clinical trial in healthy volunteer	J Immunol 2004
	Fusion protein: Ag85 – ESAT-6	Mild side effects	GMP production	Infect Immun 2001

Abbreviations: BCG, Bacille Calmette-Guérin; HIV, human immunodeficiency virus; Ag, antigen; MVA, modified vaccinia Ankara; Ph, phase.

In 2012, at least six different TB vaccine candidates both live and subunit vaccines, have completed initial phase I clinical trials, three are currently in phase II trials. Most of the new vaccines will at least initially be given as booster doses on top of a priming BCG vaccination. A virus vectored booster vaccine candidate has recently entered an early efficacy (phase IIb) trial and we would soon know if this vaccine provides an advantage over BCG. In an optimistic scenario, i.e., assuming that at least one of the first generation candidates successfully completes phase III (efficacy) evaluation, licensure of a new TB vaccines is anticipated around 2014–15. Until that time, extensive resources are needed to conduct reliable clinical trials in developing country settings. As with other vaccines targeting diseases of poverty, particular efforts in the areas of financing, production capacity logistics, etc., must be made to ensure that once a new TB vaccine is available it can be implemented rapidly with high coverage rates.

### IN A NUTSHELL

1. Conventional BCG vaccine is a part of universal immunization program.
2. It is given intradermal in dose of 0.1 mL at insertion of left deltoid.
3. Scar visually develops by 3 months. However, absence of scar does not indicate absence of immunity.
4. Conventional BCG vaccine does not prevent primary TB infection.
5. BCG has a definite predictive role against disseminated TB disease.
6. It also prevents serious forms of TB like tuberculous meningitis and miliary tuberculosis.
7. Immunity lasts for 10–15 years.
8. Revaccination is not indicated.
9. Efficacy is hindered by environmental mycobacteria like atypical mycobacteria.
10. Limitations of conventional BCG vaccine have reconstructed research on development of newer vaccines.

## Chapter 23.7

# Poliovirus Vaccines

Puneet Kumar, Vipin M Vashishtha

Inactivated poliovirus vaccine (IPV) and live oral poliovirus vaccine (OPV) are the two effective vaccines against poliomyelitis that have ensured remarkable decline in the global burden of disease in last five decades. India reported its last case of wild poliovirus (WPV) on January 13, 2011. Both these vaccines are complementary to each other and have unique roles to play, both at individual and community level. This chapter would describe both of these in brief, with special focus on Indian scenario.

## ORAL POLIOVIRUS VACCINE

Oral poliovirus vaccine consists of live attenuated strains of polioviruses (called vaccine polioviruses or Sabin viruses) grown in monkey kidney cell cultures and stabilized with magnesium chloride. These vaccine strains were developed in 1950s by Albert Sabin in Cincinnati in the USA. Of note, Sabin never patented these strains and in fact, donated these strains to Soviet Union in 1959, then to Pasteur Institute of India in Coonoor (Tamil Nadu) in 1974 and finally donated them along with *proprietary ownership* to the World Health Organization (WHO) in 1979. Initially, monovalent OPV (mOPV) was developed and later, trivalent OPV (tOPV) was developed containing all the three types (types 1, 2 and 3) of polioviruses. When tOPV was formulated, it was found that type 2 strain inhibits immune response to types 1 and 3. Thus, it was *balanced* by including maximum virus particles [1,000,000 cell culture median infectious dose (CCID<sub>50</sub>) of type 1, minimum (100,000 CCID<sub>50</sub>) of type 2 and intermediate number (300,000 CCID<sub>50</sub>) of type 3, i.e., ratio of 10:1:3. WHO revised this ratio to 10:1:6 by increasing type 3 virus particles (600,000 CCID<sub>50</sub>) in 1980s. Since then all tOPV that is manufactured anywhere has the same constitution. Since WHO *owns* the Sabin viruses, every manufacturer needs to take WHO approval regarding the constitution of OPV. This is unlike all other vaccines, where it is the manufacturers who decide the formulation and the dose content of the vaccines they make.

## Immunogenicity and Efficacy

### Global

Vaccination with tOPV results in type-specific immunity to the type that is *taken* by the intestinal mucosa. There is no cross-protection between types. Moreover, unlike most other vaccines (including IPV), its immunogenicity shows marked variation in various regions of the world and even within the country. In temperate countries with high degrees of sanitation, its efficacy is very high.

### Tropical Countries including India

In tropical and subtropical countries with poor sanitation, the efficacy is low. Data from the composite of Vellore studies in 1970s and 1980s suggest that seroconversion rates after three doses of OPV average 65%, 95% and 67% for types 1, 2 and 3, respectively. Using this data, it was calculated that in order to reach near 100% seroconversion using tOPV, it would need about 13–15 doses for types 1 and 3, while only five doses are sufficient to reach that level for type 2 poliovirus. Thus, it is not surprising that we have achieved eradication of type 2 WPV globally in as early as 1999, while the feat is not yet achieved for type 1. **Figure 1** depicts comparative immunogenicity of OPV in developed and developing (tropical) countries.

**Figure 1** Immunogenicity of oral polio vaccine (OPV) in developed and developing (tropical) countries

The incremental responses to sequential doses of OPV shown as "seroconversion index (SI)". Seroconversion Index (SI): (No. of seroconverted to types 1+2+3 × 100)/(No. seronegative to types 1+2+3 before immunization);

The top curve shows the pattern of developed countries. SI is fixed at 80 for first dose and also for subsequent doses. SI after two doses 96, after three doses 99. The curve below with triangle shows SI to OPV in children in developing countries (example Vellore, TN, India). SI after first dose 37, two doses 54, three doses 78, and after five doses 87.

The curve with dark dots shows the SI calculated arithmetically for subsequent doses using SI 37 for each dose. For example, SI after two doses =  $37 + [37(100-37)]/100 = 60$ ; SI after three doses =  $60 + [37(100-60)]/100 = 75$ , SI after four doses 84, after five doses 90, after six doses 94, after seven doses 96. Response to sequential doses increases by "arithmetic proportion" principle—Decreasing numbers respond to each additional dose; titres remain low to moderate—Small proportions always fail; we have confirmed wild virus polio after 10, 18, even 24 doses

(Reproduced with permission from John TJ. Immunization against polioviruses in developing countries. Rev Med Virol. 1993;3:149-60.)

Even within India, there is a large variation in its efficacy across different regions. While the per-dose vaccine efficacy has been found to be about 30% in Vellore, it was just around 10% in some regions of Uttar Pradesh and Bihar, the two *hotspots* of polio in India. It has also been shown that the vaccine efficacy of a geographical location remains stable over decades. The poor immunogenicity in some states is not just due to poor routine immunization (RI) coverage and breaks in cold chain, as previously thought. Many experts believe that the reason for poor immunogenicity in certain areas is some unknown defect in gut-related immunity; however another school of thought is just the opposite: It has been suggested that *good* mucosal immunity, that remains on *high alert* on account of frequent enteric infections prevents infection by vaccine viruses (vaccine virus *take*), an essential first step before the immune response can be expected. Another reason cited for poor efficacy in some regions of India includes high incidences of diarrhea, malnutrition and high population density. Presence of other nonpolio enteroviruses inhibits proper *uptake* of Sabin polio viruses contained in OPV. Thus, both *failure of the vaccine* as well as *failure to vaccinate* results in poor efficacy epidemiologically.

### Mucosal Immunity

Being an oral live vaccine, OPV induces mucosal immunity also, i.e., it induces production of secretory immunoglobulin A (IgA) locally in the mucosa. Thus, OPV is capable of providing *better* herd immunity as compared to IPV and is capable of

preventing infection with WPV (*breaking the transmission chain*) in addition to offering personal protection against paralytic poliomyelitis. However, the mucosal immunity is short lived unlike long-term systemic immunity and is not as *solid* as humoral immunity. Thus, while humoral immunity fully protects an individual from disease (paralytic poliomyelitis), possibly for life, but mucosal immunity is not 100% dependable in protecting against repeat infection and breaking the transmission chain.

### Herd Immunity and Contact Immunity

*Herd immunity* should not be confused with *contact immunity*, a related concept wherein a vaccinated individual can *pass on* the vaccine to another individual through contact. Not all vaccines possess this virtue which is mainly the quality of certain live, attenuated vaccines that shed very efficiently either through gut or nasal mucosa though still producing *herd effect* and contributing in generation of *herd immunity*. OPV has got this unique quality and provides efficient *contact immunization*. On the other hand, IPV despite providing *herd immunity* and *herd effect*, does not provide *contact immunity*. The greater the transmissibility of a vaccine organism, the higher the contact immunization or contact immunity.

### Onset and Duration of Protection

Oral poliovirus vaccine has a much faster onset of action as compared to IPV, making it the vaccine of choice for outbreak control. Being a live vaccine, it is expected to offer lifelong protection. However, data from developed countries show there is gradual decline in the humoral antibodies level amongst vaccinees and they decline sometimes to almost undetectable levels after decades. However, these individuals continue to remain protected for lifelong against the paralytic disease despite having very low level of antibodies. There is no data from developing countries on duration of protection.

*Monovalent OPVs (mOPVs) and bivalent OPV (bOPV, for types 1 and 3)* are more efficacious than tOPV, as the inhibitory effect of type-2 is eliminated. In addition, elimination of type-2 also eliminates the risk of vaccine-associated paralytic poliomyelitis (VAPP) due to type-2 virus and reduces the risk of vaccine-derived polioviruses (VDPV) (*vide infra*) remarkably, since over 90% of cases of VDPV are due to type-2 virus only. Thus, mOPV for types 1 and 3 were introduced in India in 2005 and bOPV (developed and tested in India) is being used for pulse immunization since 2010. Their induction in the sub-National immunization days (SNIDs) and other supplementary immunization activities (SIAs) was amongst the main reasons behind disappearance of paralytic polio from India.

### Safety

OPV is well tolerated without any gastrointestinal side effects. However, it is associated with a rare, but well recognized serious adverse effect, VAPP.

### Vaccine-associated Paralytic Poliomyelitis

Vaccine-associated paralytic poliomyelitis is defined as those cases of acute flaccid paralysis (AFP) which have residual weakness 60 days after the onset of paralysis and from whose stool samples, vaccine-related poliovirus but no WPV is isolated. Clinically, it is indistinguishable from WPV polio. It is caused by deattenuation of the vaccine viruses during replication in the gut. It may occur in the vaccine recipient (recipient VAPP) or close contact of the vaccine recipient (contact VAPP). Conventionally, it is believed that the type-3 virus is the most common cause of

recipient VAPP and type-2 is the most common cause of contact VAPP. However, the epidemiology of polio in recent times revealed that type-2 was mainly responsible for VAPP in India and elsewhere.

The risk of developing VAPP also shows geographic variations. In developed nations the risk of VAPP is higher with the first dose of OPV and the risk decreases sharply (> 10-fold) with subsequent OPV doses, whereas in developing countries this decline is more gradual, probably as a consequence of lower vaccine effectiveness. Most of VAPP cases in India were associated with subsequent OPV dose, not first dose. The incidence of VAPP has been estimated at 4 cases per million birth cohort per year in countries using OPV. The incidence of VAPP in developed countries, such as USA, has been reported to be 1 per 2.4 million doses distributed and 1 per 750,000 with first dose. The risk of VAPP in India has been estimated to be 1 per 4.1–4.6 million doses distributed and 1 per 2.8 million first dose, and subsequent-dose recipient risk is found around 1 case per 13.9 million. This comparatively lower risk of VAPP has been attributed to maternal antibodies, birth dose of OPV, early immunization with OPV and most importantly lower *take* of the vaccine (as only the vaccine that takes up can cause VAPP). Nevertheless the absolute numbers of VAPP are high and it is estimated that 181 cases of VAPP occurred in India in 1999. Moreover, if the risk of VAPP is calculated *per-million birth cohort* (rather than *per-million doses distributed*), the risk is then higher in India than in Western world, simply because our babies are getting more number of OPV doses every year as compared to West in OPV era: thus our babies are at higher risk!

### Vaccine-derived Poliovirus

Viruses causing VAPP have low transmissibility despite being neurovirulent. The fact that this property of low transmissibility of Sabin viruses can also revert along with regaining neurovirulence was predicted long back by an Indian scientist. However, it was not well understood by the experts, until the year 2000 when one such virus resulted outbreak of polio in children in the Hispaniola Island (Haiti and Dominican Republic); such reverted Sabin-derived virus causing polio outbreak was named VDPV. Since then, over 18 outbreaks of VDPVs have been reported from 16 countries, affecting 699 children. India has reported 37 cases. Type 2 virus is the cause of VDPV in 85–90% cases. Currently, VDPVs are classified into three groups: (1) circulating VDPV (cVDPV)—VDPV with evidence of virus circulation in the population causing two or more paralytic cases; (2) iVDPV—VDPV in the immunodeficient person; and (3) VDPV of ambiguous origin (aVDPV)—VDPV isolated from environmental sources or evidence of circulation not established.

### INACTIVATED POLIOVIRUS VACCINE

Inactivated poliovirus vaccine consists of poliovirus grown in monkey kidney cell/human diploid cells and killed by formaldehyde. It was developed by Jonas Salk in 1950s in the USA. In the *first generation IPV* polioviruses were grown in primary monkey kidney cell cultures and had water-in-oil emulsion as adjuvant. It was very immunogenic having 80–90% efficacy against paralytic disease and 70% against any disease after two doses. Because of presence of adjuvant, the *old IPV* was very painful. Thus, *second generation IPV* was developed without adjuvant, but it required three doses for adequate seroconversion. The modern-day, *third generation IPV* [also called as enhanced IPV (eIPV)] was developed by Dutch scientist Anton von Wezel in 1978 which was not only more potent but was more refined

too. *eIPV* is the current vaccine in use all over the globe now. In this, Vero cell line replaced the monkey kidney cells. Moreover, the virus was purified before inactivation and vaccine potency was standardized in experimental laboratory animals. Currently available IPV is this third generation IPV (*eIPV*), containing 40, 8 and 32 D antigen units of type 1, 2 and 3 respectively without any adjuvant.

Very recently, *fourth generation IPV* has also been developed. In this, Sabin virus strains are used instead of laboratory maintained WPVs, and thus is called Sabin-IPV. This has an obvious advantage in the event of laboratory leak of viruses from the manufacturing sites. Thus, manufacturing such vaccine would require less strict biosafety mechanisms and could be more freely manufactured all over the world including in developing countries. Japan is the only country that is already using this Sabin-IPV, while Chinese manufacturers are also conducting trials of similar vaccine.

Most of the brands of IPV available are stand-alone IPV. However, many different combinations (and even hexavalent: DTaP/Hib/IPV/HBV) are available and are in use in some countries. There is no DTwP-IPV combination anywhere in the world, although India and France did develop one such IPV that could be mixed with DTwP and was even manufactured in India in early 1980s. Currently available preparations of IPV do not contain any adjuvant but do contain thiomersal as preservative. Since thiomersal affects IPV potency, in combination products with DTP it is either avoided or replaced with 2-phenoxy-ethanol.

### Immunogenicity and Efficacy

Inactivated poliovirus vaccine is one of the most immunogenic vaccines, and since it is known that virus neutralizing antibody in the blood stream is highly protective against paralytic polio, immunogenicity parallels protective vaccine efficacy in case of polio vaccines. Studies have shown that just two doses at 2 months interval achieve nearly 100% seroconversion to all the three serotypes. However, if the vaccination is started at 6 weeks of age [as in Expanded Program on Immunization (EPI) schedule], then there is some interference with maternal antibodies and thus, three doses are required. Further, since the interval between the second and third dose is 1 month rather than ideal gap of 2–4 months, a booster is needed at 15–18 months for optimum results. **Table 1** shows impact of maternal antibodies on seroconversion of IPV during two trials of IPV (old and enhanced) in India. IPV was licensed in USA, Canada and several European countries in 1955; wherever it was systematically used in children polio incidence declined by over 95%.

**Table 1** Impact of maternal antibodies and interval between doses on seroconversion of inactivated poliovirus vaccine (IPV)

Vaccine	Maternal antibodies	Interval between doses (weeks)	
		4 weeks	8 weeks
Old IPV (3 doses)	Present	66%	95%
	Absent	95%	99%
<i>eIPV</i> (2 doses)	Present	87%	87%
	Absent	96%	96%

Abbreviations: IPV, inactivated poliovirus vaccine; *eIPV*, enhanced potency inactivated poliovirus vaccine.

Adapted from John TJ. The golden jubilee of vaccination against poliomyelitis. Indian J Med Res. 2014;119(1):1–17.

Conventionally, it is believed that IPV does not induce strong mucosal (intestinal) immunity. Hence, it is not suitable for interruption of wild virus transmission especially in tropical countries. OPV is considered a *vaccine of choice* by virtue of possessing an excellent mucosal immunity. However, it has been found that IPV also induces intestinal mucosal immunity which results from transudation or *spillover* of serum antibodies (IgM, IgG and nonsecretory IgA) on mucosal surfaces and secretions. Nevertheless, since secretory IgA is not induced, this is often labeled as *mucosal protection* rather than *mucosal immunity*. It has also been suggested that there may be some other mechanisms other than IgA to induce mucosal immunity. In fact, contrary to the conventional wisdom, studies have shown that IPV also induces excellent *herd effect*. This has been demonstrated in large national-level vaccine programs like in Finland where paralytic disease disappeared with even a modest 51% of national coverage with three doses of IPV in 1961 without ever using OPV. Many experts argue now that *mucosal immunity* may not be as important in overall protection against the disease as believed so far, and it is the *humoral immunity* that ultimately determines protection against wild disease.

### Duration of Protection

Information on the duration of IPV-induced protection originates only from industrialized countries. Circulating antibody persist for decades (possibly for life), but antibody titers decrease overtime, so some adults may lack detectable antibody; typically they first lose antibody to type-3 poliovirus. However, as with OPV, these individuals remain protected against paralytic disease. There is no data from developing countries on this attribute.

### Safety

IPV (all generations) has an exceptionally clean record of safety. As it is unadjuvanted vaccine, local injection site reactions and pain are minimal, if any. The purification processes get rid of cell debris and cellular deoxyribonucleic acid (DNA), etc. IPV contains trace amounts of streptomycin, neomycin and polymyxin B, allergic reactions may be seen in individuals with hypersensitivity to these antimicrobials. There is no risk of VAPP or VDPV with this vaccine. A detailed comparative evaluation of both the polio vaccines is provided in **Table 2**.

### POLIO “END GAME” STRATEGIES

Since India has fully interrupted the WPV transmission and has been declared a polio-free country by the WHO, the time to withdraw OPV is approaching fast, considering the safety issues (VAPP and VDPV) associated with continuation of OPV in post-eradication scenario. The process of gradual withdrawal of OPV synchronously from all over the world without exposing children to the risk of wild or vaccine-derived polio is the greatest concern to the global polio eradication initiative (GPEI). This process and strategies involved in the transition from OPV to IPV all over the globe is referred as *end game* in polio parlance. The recently launched, *Polio Eradication and Endgame Strategic Plan, 2013–2018* provides strategic framework for the sequential cessation of Sabin strains, starting with Sabin type 2. For Sabin type 2, cessation means that tOPV must be replaced with bOPV in a synchronized manner globally. For risk mitigation, the framework includes at least one dose of IPV included in the routine EPI (starting >6 months before switch from tOPV to bOPV). Hectic preparations

**Table 2** Comparative evaluation of oral polio vaccine (OPV) and inactivated poliovirus vaccine (IPV)

Attributes	OPV	IPV
<b>Efficacy issues</b>		
Potency	Low (needs 4 or more doses)	High (needs 2 or 3 doses)
Systemic immunity	Variable (high in industrialized countries; low in tropical countries)	High
Predictability of immune responses	Low, variable	Highly predictable
Mucosal immunity	Excellent (both pharyngeal and intestinal)	Low (low intestinal but good pharyngeal)
Contact immunization	Yes (community protection)	No (individual protection)
Onset of action	Faster	Comparatively slower
Duration of protection	Long, possibly life-long	Long
<b>Safety issues</b>		
Risk of VAPP	Yes	No
Risk of cVDPV	Yes	No
Risk of use in bioterrorism	No	Yes (produced with wild virus seeds)
Requirement of Biosafety measures	Less stringent	Stringent (BSL-3)
<b>Administration issues</b>		
Extra injection	No	Yes (in stand-alone preparation is used)
Possible combination vaccine	No	Yes
Injection safety issues	No risk	A risk
Compliance	Excellent	May be reduced if used as stand-alone preparation
Suitability for large scale campaigns	Yes	No
<b>Other issues</b>		
Cost	Low	High
Availability	Good (many manufacturers even in developing countries)	Scarce (only two major manufacturers)

Abbreviations: VAPP, vaccine-associated paralytic poliomyelitis; cVDPV, circulating vaccine-derived polioviruses; BSL, biosafety level.

are going on to introduce at least one dose of IPV at the time of third dose of DTP in the Universal Immunization Program (UIP) in India at the earliest.

## SCHEDULES OF POLIO VACCINES

### Dose

The dose of OPV is two drops orally: for routine vaccination, supplementary vaccination as well as for travelers. The dose of IPV is 0.5 mL to be administered intramuscularly/subcutaneously. All the currently available brands of IPV in India are packaged in prefilled syringe.

## National Immunization Schedule

The national immunization schedule (UIP schedule) has not introduced IPV as of now. As per UIP schedule, OPV is given at birth, 6, 10 and 14 weeks followed by booster at 15–18 months. It is planned to introduce IPV in national schedule somewhere around first quarter of 2015. In addition to RI, all OPV doses (mono-, bi- or trivalent) offered through supplemental immunization activities (SIAs: *pulse polio*), should also be given to all children below 5 years of age, regardless of previous RI.

## The Indian Academy of Pediatrics Schedule for Office Practice

The Indian Academy of Pediatrics (IAP) has recommended *sequential IPV-OPV schedule* in its 2012 and 2013 guidelines as a step before complete withdrawal of OPV. This is in accordance with strong evidence that sequential schedules that provide IPV first, followed by OPV can prevent VAPP while maintaining the critical benefits conferred by OPV (i.e., high levels of gut immunity). As per this schedule, OPV is to be administered at birth, three primary doses of IPV at 6, 10 and 14 weeks, followed by two doses of OPV at 6 and 9 months, another dose (booster) of IPV at 15–18 months and OPV at 5 years. IAP continues to recommend the birth dose of OPV, since giving OPV dose at a time when the infant is still protected by maternally-derived antibodies may, at least theoretically, also prevent VAPP. Though OPV at birth is not immunogenic, it enhances seroconversion of subsequent polio vaccines, both OPV and IPV considerably. A birth dose of OPV is considered necessary in countries where the risk of poliovirus transmission is high.

If IPV is started after 8 weeks, then only two doses at 2 months interval are sufficient as primary doses, since there is no interference from maternal bodies that occurs when it is started at 6 weeks; booster is recommended at 15–18 months of age. For any unimmunized child less than the age of 5 years, IPV can be offered as *catch-up* vaccination. The schedule in such a case is two doses at 2 months interval followed by booster 6 months after the last dose.

In case, IPV is unavailable or unaffordable, the primary series must be completed with three doses of OPV given at 6, 10, and 14 weeks. Boosters of OPV are recommended at 15–18 months of age and at 5 years of age.

OPV is contraindicated in immunodeficient patients (especially humoral immunodeficiencies) and their household contacts.

Countries using IPV only in their schedules usually recommend three doses (at 2/4/6 months or 2/3/5 months of age) followed by booster at 4 years of age.

Since India is now a *polio free* country, IAP has specific recommendations for travelers to polio-endemic countries or areas:

- For those who have previously received at least three doses of OPV or IPV should be offered another dose of polio vaccine as a once-only dose before departure.
- Nonimmunized individuals should complete a primary schedule of polio vaccine, using either IPV or OPV. Primary series includes at least three doses of either vaccine.
- For people who travel frequently to polio-endemic areas but who stay only for brief periods, a one-time only additional dose of a polio vaccine after the primary series should be sufficient to prevent disease.

Government of India has made it mandatory for all travelers to and from polio endemic countries (Afghanistan, Nigeria and Pakistan) and countries with wild polio virus circulation following importation (Ethiopia, Kenya, Somalia and Syria) to take one dose of OPV at least 4 weeks prior to departure to or from these countries. OPV vaccination certificate issued after such additional dose remains valid for 1 year. This additional dose is must for

travelers of all ages, even adults. This is because of the fact that even adults can acquire infection with poliovirus and transmit WPV to others, even though paralytic polio is rare in children above 5 years of age. These requirements are effective for all travels from March 2014. Similar recommendations on a global level have been issued by the WHO under the International Health Regulations on May 5, 2014. The WHO lists Cameroon, Equatorial Guinea and Israel also as polio-infected countries in addition to seven countries named earlier.

### IN A NUTSHELL

1. Inactivated poliovirus vaccine (IPV) and live oral poliovirus vaccine (OPV) are highly efficacious vaccines against poliomyelitis.
2. Initially, monovalent OPV (mOPV) was developed and later, trivalent OPV (tOPV) was developed containing all the three types (types 1, 2 and 3) of polioviruses.
3. OPV shows marked variation in its immunogenicity in various regions of the world and even within the country. Its efficacy is highest in industrialized, temperate countries whereas lowest in tropical, developing countries.
4. OPV induces excellent gut mucosal immunity and thus provides better *herd immunity* as compared to IPV. It also produces good *contact immunity* by contact immunization.
5. Monovalent OPVs (mOPVs) and bivalent OPV (bOPV, for types 1 and 3) are more efficacious than tOPV, as the inhibitory effect of type-2 is eliminated. Induction of these *new* OPVs greatly facilitated wild poliovirus elimination in India.
6. Vaccine associated paralytic poliomyelitis (VAPP) and vaccine-derived poliovirus (VDPV) are two serious side effects of OPV.
7. Original Salk's IPV developed in 1950s was highly immunogenic having 80–90% efficacy against paralytic disease and 70% against any disease after two doses.
8. The modern-day, third generation IPV, *enhanced IPV (eIPV)* is not only more potent but more refined too. It is the current vaccine in use all over the globe now. Studies have shown that just two doses started at 2 months of age and at 2 months interval achieve nearly 100% seroconversion to all the three serotypes.
9. The greatest virtue of IPV is its predictable immunogenicity, without being affected much by geographic locations, and extreme safety free from serious side effects like VAPP and VDPV of OPV. IPV also induces good pharyngeal and some useful intestinal mucosal immunity. Studies have also shown that IPV also induces excellent *herd effect*.
10. The process and strategies involved in the transition from OPV to IPV all over the globe is referred as *end game* in polio parlance. The *new endgame* strategies include *parallel* rather than *sequential* risk management.

## Chapter 23.8

# Diphtheria, Tetanus and Pertussis Vaccines

Puneet Kumar, Vipin M Vashishtha

Introduction of diphtheria, tetanus and pertussis (whooping cough), DTP or DPT or DTwP (DTwP is a type of DTP vaccine) vaccine in 1940s and subsequent adoption in expanded program on immunization (EPI) leading to increased global coverage made tremendous impact on morbidity and mortality due to diphtheria, tetanus and pertussis. While tetanus has virtually disappeared, diphtheria as a childhood disease remains fairly well controlled (with some evidence of an epidemiological shift affecting adolescents and adults). Pertussis, on the other hand, has resurfaced in highly immunized populations in the recent years and is now under intense scrutiny. Coverage with three doses of the whole cell vaccine (DTwP vaccine) in India is still low (71.5%) and only 41.4% children in the age group of 18–23 months had received first DTWp booster. The need of completing the schedule and boosters should be stressed upon by the pediatrician. This chapter would briefly describe all the vaccines against these infections, with special focus on Indian scenario.

### DTwP VACCINE

It is composed of 20–30 Lf of diphtheria toxoid, 5–25 Lf of tetanus toxoid (TT) and inactivated whole cell pertussis bacilli adsorbed on insoluble aluminum salts as adjuvant.

### Immunogenicity and Efficacy

For diphtheria and tetanus, the protective levels of their respective antitoxins have been defined as more than 0.1 IU/mL and more than 0.01 IU/mL, respectively. Studies have demonstrated immunogenicity as well as clinical efficacy (in outbreak settings) of three properly spaced doses of the vaccine to be above 95% for these two infections. Disease may occur in vaccinated individuals but is milder.

In contrast, the scenario of pertussis is complex. First, unlike *C. diphtheriae* and *C. tetani*, *B. pertussis* has multiple virulence factors, viz., pertussis toxin (PT), filamentous hemagglutinin (FHA), pertactin (PRN), fimbriae (FIM) type 2 and type 3, adenylate cyclase toxin (ACT), tracheal cytotoxin (TCT), BrkA (Bordetella resistance to killing genetic locus, frame A), lipooligosaccharide and *B. pertussis* endotoxin. Second, the bacillus alters its phenotypic state depending upon environmental conditions, and may show different expression of virulence factors under different conditions. Third, the exact pathogenesis of pertussis is incompletely understood even today: this makes the relative role of various virulence factors to be unclear. Thus, there is no single absolute or surrogate correlate of protection known for pertussis disease and vaccines till date. Antibody levels against PT, PRN and FIM can be used as markers of protection, but no established protective antibody levels are known. Hence, it is difficult to define *immunogenicity* of pertussis vaccines accurately.

Assessment of clinical efficacy of pertussis vaccine is equally complex, since laboratory diagnosis of pertussis is difficult and the facilities are virtually absent in the developing world. The diagnosis invariably remains clinical and the sensitivity and specificity varies with the case definition used. Accordingly, the efficacy estimates also vary considerably with different case definitions used in different studies. This also makes the comparison between different studies difficult. The efficacy estimates have varied from 83% to 98% in higher efficacy trials to as low as 36–48% in lower efficacy trials. According to a 2003 systematic review, the pooled efficacy of wP vaccine against pertussis in children was 78%, but efficacy varied significantly among vaccines. The efficacy of wP alone ranged from

61% to 89%, and the efficacy of combination DTWp vaccines ranged from 46% to 92%. Further evidence of the efficacy of wP vaccine is provided by the observation that the reported incidence of pertussis disease varies inversely with vaccine acceptance rates. There is no data on the effectiveness of wP vaccines among older age groups since pertussis was previously perceived as a problem only of young children, and the reactogenicity of wP vaccine was thought to be too high to permit routine use in older children, adolescents and adults.

### Duration of Protection

Immunity against all three components has been documented to wane over 6–12 years and hence regular boosting is recommended for all three antigens.

### Adverse Effects

Most adverse effects are due to the pertussis component. Minor adverse effects like pain, swelling and redness at the local site, fever, fussiness, anorexia and vomiting are reported in almost half the vaccinees after any of the three primary doses. Serious adverse effects have been reported with DTWp vaccines but are rare. The frequency of these side effects/1,000 doses is 0.2–4.4 for fever more than 40.5°C, 4–8.8 for persistent crying, 0.06–0.8 for hypotonic hyporesponsive episodes (HHE), 0.16–0.39 for seizures and 0.007 for encephalopathy. The frequency of systemic reactions reduces and that of local reactions increases with increasing number of doses. Children with history of a reaction following vaccination are more likely to experience a reaction following future doses. Catastrophic side effects such as sudden infant death syndrome (SIDS), autism, chronic neurologic damage, infantile spasms, learning disorders and Reye's syndrome were attributed to use of the wP vaccines in the past. It has now been proved beyond doubt that the wP vaccine is not causally associated with any of these adverse events.

### Contraindications and Precautions

Absolute contraindications to any pertussis vaccination (including DTWp vaccine) are history of anaphylaxis or development of encephalopathy within 7 days following previous DTWp vaccination. In case of anaphylaxis, further immunization with any diphtheria/tetanus/pertussis vaccine is contraindicated as it is uncertain which component caused the event. For patients with history of encephalopathy following vaccination, any pertussis vaccine is contraindicated and only diphtheria and tetanus vaccines may be used. Events such as persistent inconsolable crying of more than 3 hours duration/hyperpyrexia (fever >40.5°C)/HHE within 48 hours of DTWp administration and seizures with or without fever within 72 hours of administration of DTWp are considered as precautions but not contraindications to future doses of DTWp because these events generally do not recur with the next dose and they have not been proven to cause permanent sequelae. Progressive/evolving neurological illnesses, is a relative contraindication to first dose of DTWp immunization. However, DTWp can be safely given to children with stable neurologic disorders.

### DTaP VACCINES

Good coverage of DTWp vaccines in developed countries led to remarkable decline in incidence of all the three infections in second half of the last century. With only few cases being reported, the frequent local side effects of the vaccine became increasingly unacceptable to the society leading to decline in coverage of the vaccine in some of the developed countries and resurgence of these infections, especially pertussis. This led to the development of less reactogenic acellular pertussis containing DTaP (*a* for acellular) vaccines starting with Japan in 1981 and then by 1996 in USA.

DTaP vaccines contain at least one of the separately purified antigens PT, FHA, PRN, and fimbrial hemagglutinins 1, 2 and 3 (FIM type 2 and type 3), in addition to diphtheria and tetanus toxoids as

in DTwP vaccines. Although DTaP vaccines contain only a subset of 1–5 antigens, in contrast to DTwP vaccines that contain entire complement of approximately 3,000 antigens, the *concentration* of the antigens in DTaP vaccines is much higher. Hence, while DTwP vaccines can be considered as vaccines with *broad coverage* but low titers, DTaP vaccines have *narrow coverage* but high titers. Among different DTaP vaccines also there is lot of variations. They differ from one another not only in the number and quantity of antigen components, but also with regard to the bacterial clone used for primary antigen production, methods of purification and detoxification, incorporated adjuvants, and the use of preservatives, such as thiomersal. Nearly two dozen DTaP vaccines have been designed and tested, but direct comparison between these products is almost impossible due to several variables listed earlier. Further, the exact contribution of the different aP antigens to protection is not clear and thus there is no consensus as yet about the antigenic composition of an ideal aP vaccine, although it is clear that PT is the most important antigen. Among the DTaP vaccines that are licensed in India, Pentaxim® is 2-component DTaP [in combination with inactivated polio vaccine (IPV) and reconstituted with *Haemophilus influenzae* type b (Hib) conjugate vaccine], Infanrix® is 3-component, while Tripacel® is 5-component DTaP vaccine.

### Efficacy

This is the topic being hotly debated globally in view of outbreaks of pertussis in highly vaccinated countries like USA, Australia, New Zealand and some European countries which have been using DTaP in their national programs for more than a decade. The efficacy trials conducted in Europe and Africa have brought out variable results and are not strictly comparable due to lot of variation between different DTaP vaccines tested, variation in the DTwP products with which former have been compared and variations in case definition used. Moreover, no study has evaluated a multicomponent vaccine directly against versions of itself that contain alternate components or different quantities of each component. Although these limitations have precluded a formal meta-analysis of the efficacy data, a recent Cochrane Review has suggested that the efficacy of multicomponent ( $\geq 3$ ) vaccines varied from 84% to 85% in preventing typical whooping cough (characterized by 21 or more consecutive days of paroxysmal cough with confirmation of *B. pertussis* infection by culture, appropriate serology or contact with a household member who has culture-confirmed pertussis), and from 71% to 78% in preventing mild pertussis disease (characterized by seven or more consecutive days of cough with confirmation of *B. pertussis* infection by culture or appropriate serology). In contrast, the efficacy of one- and two-component vaccines varied from 59% to 75% against typical whooping cough and from 13% to 54% against mild pertussis disease. Multicomponent acellular vaccines are more effective than low-efficacy whole-cell vaccines, but may be less effective than the highest-efficacy whole-cell vaccines.

Recent studies have also suggested that the efficacy of DTaP vaccines is especially low when they are used in primary series of the vaccination. Children *primed* with whole cell pertussis vaccine were better protected from pertussis during the recent outbreaks in comparison to those who received acellular pertussis vaccines throughout. Those who received even one (first dose) of whole cell pertussis vaccine, followed by acellular vaccine in subsequent doses were found to be better protected, and this difference was statistically significant in many studies conducted as a part of retrospective analyses in USA and Australia after the recent outbreaks. Recent analysis of epidemiological data of 54 countries has also clearly demonstrated that there is a statistically significant correlation between use of DTaP vaccine used as the first (priming) dose and resurgence of pertussis in the respective countries in last two decades. Thus, it is being suggested that the immune response to acellular and

whole-cell priming might be different. The lesser protection provided by acellular pertussis vaccines, both as the initial vaccine or full primary course, may be due to *linked epitope suppression*, when the initial exposure locks in the immune response to certain epitopes and inhibits response to other linked epitopes on subsequent exposures. It has also been shown that in contrast to DTwP vaccines that induce immune response with Th1 and Th17 bias, DTaP vaccines induce predominantly Th2 (antibody producing) immune response. This might also be in some way be involved in different *priming* when DTaP vaccine is used as the first dose.

Recent animal studies have also shown that the immune response to currently available DTaP vaccines is much less effective in preventing infection/colonization with *B. pertussis* than current DTwP vaccines. It is also less effective in mucosal clearance of pertussis infection. These two factors make current DTaP vaccines less effective in reducing transmission of infection as compared to currently available DTwP vaccines, even though the difference might be less in preventing pertussis. This *might* be the missing link explaining the recent resurgence/outbreaks.

### Duration of Protection

Data from developed countries suggests that protection after DTaP vaccination wanes after 4–12 years. Similar data from developing countries is lacking as on date.

### Adverse Effects

The incidence of minor adverse effects (pain, swelling and redness at the local site, fever, fussiness, anorexia and vomiting) is about 66% less than with DTwP vaccine, but incidence and severity of local adverse effects increases with each successive dose of DTaP vaccine, as with DTwP vaccines. The incidence of severe adverse effects (persistent crying, hypotonic hyporesponsive episodes, seizures and encephalopathy) is same as with DTwP vaccines. Contraindications and precautions are same as with DTwP vaccines.

### DT VACCINE

This vaccine comprises of diphtheria and tetanus toxoid in similar amounts as in DTwP/DTaP, but lacks the pertussis component totally. It is recommended in children below 7 years of age where pertussis vaccination is contraindicated.

### Td AND Tdap VACCINES

Good coverage with DTP vaccines in a population breaks the transmission cycle and reduces natural circulation of these infections in young children. Moreover, the immunity to all the three infections is known to wane after 6–12 years after last booster (more rapidly with DTaP vaccines). This results in pooling of susceptible adolescents and adults in these populations. Thus, infrequent *natural boosting* and rapid waning of immunity acquired from childhood vaccination increases the incidence of these *childhood infections* (diphtheria and pertussis) in adolescents and adults. Secondly, the partly protected adolescents and adults also act as *reservoirs* as a disease transmission to unvaccinated/partially vaccinated young infants. Third, when childhood vaccination programs break down as happened in the former Soviet Union in the early 1990s, massive outbreaks of diphtheria involving primarily adults have occurred. Recent outbreaks of pertussis in several countries have also affected adolescents majorly. Thus it is desirable to regularly boost adult immunity against diphtheria and pertussis in addition to tetanus every 10 years. In addition, vaccination against diphtheria and tetanus is also needed for catch-up vaccination in unimmunized/partially immunized children. Vaccinating pregnant women with diphtheria and pertussis vaccine (in addition to tetanus) can also protect their newborn babies against these infections before the age

of 6–8 weeks when routine immunization begins. However, DTP vaccines (both DTwP and DTaP) and DT vaccines have increased reactogenicity in older children and are thus not recommended in children above 7 years of age. Thus, tetanus-diphtheria (Td) and tetanus-diphtheria-pertussis (Tdap) vaccines were developed. Td contains the usual dose of TT and only 2 Lf units of diphtheria toxoid (instead of 20–30 Lf in childhood vaccines) and is available in India as SII Td-vac<sup>®</sup>. Tdap vaccines contain standard quantity TT and reduced quantity diphtheria and acellular pertussis vaccine. The two brands available in India are Boosterix<sup>®</sup> and Adacel<sup>®</sup>.

### Efficacy and Effectiveness

Tdap vaccine was licensed first time in May 2005. The coverage of this vaccine in the USA was 40.8% in 2008 which has increased to 84.6% in 2012. Hence, the efficacy and effectiveness data is also limited. This limited data suggests only modest efficacy (in the range of 65–75%) of the pertussis component of Tdap. The preliminary data suggest effectiveness wanes very rapidly (within 3–4 years) among aP vaccine recipients and there was no evidence of herd immunity.

### Adverse Effects

The most common side effect with Tdap is pain at the local injection site in about 70% of vaccinees, followed by other local adverse effects like redness and swelling. Systemic side effects like fever, headache and fatigue are rarely seen. Serious adverse events have not been reported.

### Precautions and Contraindications

The Tdap vaccine needs to be used with caution in following conditions:

- Moderate or severe acute illness;
- History of an Arthus reaction following a previous dose of TT and/or diphtheria toxoid containing vaccine, including meningococcal conjugate vaccine;
- Guillain-Barré syndrome (GBS) within 6 weeks of previous dose of TT containing vaccine; and
- Progressive or unstable neurological disorder or uncontrolled seizures, until these are stabilized with medical therapy.

The contraindications are serious allergic reaction to any component of the vaccine or history of encephalopathy not attributable to an underlying cause within 7 days of administration of a vaccine with pertussis component.

### TT VACCINE

Regular boosting of immunity against tetanus *lifelong* is strongly recommended to remain protected from the ubiquitous bacteria, *Clostridium tetani*. TT was developed as early as 1914 and adsorbed TT was first licensed in USA in 1937. It contains 5 Lf of toxoid with aluminum hydroxide as adjuvant. It is very efficacious vaccine and has helped in near elimination of tetanus in most parts of the world. Tetanus is exceedingly rare in well-immunized individual. The local reactions like local pain, erythema and mild swelling are frequent but serious adverse events are exceedingly rare. Repeated doses at frequent intervals are, however, associated with profound immune complex mediated reactions like swollen limbs and fever (Arthus type 2 reactions).

## RECOMMENDATIONS FOR USE OF ALL DTP VACCINES (DTwP/DTaP/DT/TDaP/Td/TT VACCINES)

### Routine Vaccination

Indian Academy of Pediatrics (IAP) recommends three primary doses of DTP vaccines at 6, 10 and 14 weeks and two boosters at

15–18 months and 4–6 years of age. Only DTwP should be used in primary series. DTaP vaccines may be preferred to wP vaccines only in those children with history of severe adverse effects after previous dose/s of wP vaccines or children with neurologic disorders, if resources permit. The parents should be counseled about the probable efficacy related disadvantages of using aP vaccines for the primary series. In booster doses, DTaP can be considered, considering reactogenicity of DTwP vaccines. However, DTwP is preferable even for booster doses. Whenever DTaP is chosen, the vaccine with at least 3 aP components should be chosen, the more the better. DT vaccine is recommended only when pertussis vaccine is contraindicated. Under Universal Immunization Program (UIP), only DTwP is available with almost similar schedule.

In its latest update of October 2014, IAP has recommended that children who have received the prior doses of DTaP instead of DTwP should be offered DTwP for all subsequent doses. There is no need of repeating or giving additional doses of wP vaccine to boost immunity, as more doses may be associated with a risk of adverse reactions.

Globally, most of the developed countries start routine immunization at 2 months of age. Different countries follow different schedules: either 2, 3, 4 months or 2, 4, 6 months or 2, 3, 5 months schedule for primary series and boosters at 16–18 months and at 4–6 years of age. Some countries like Australia do not recommend booster at 18 months of age.

Tdap vaccine is recommended at 10 years of age by IAP, followed by Td vaccine every 10 years (lifelong). At 10 years of age, Td can replace Tdap vaccine if Tdap is not available or not affordable; TT can be used if Td is also not available. For subsequent doses also, TT can be used if Td is not available. Only TT is available under National Immunization Program of India. TT is to be given at 10 years and 16 years of age under the program.

### Vaccination in Specific Circumstances

#### Catch-up Vaccination

For unimmunized children *below 7 years of age*, three doses of DTwP/DTaP should be used (preferably DTwP) at 0, 1 and 6 months interval. The second childhood booster is not required if the last dose has been given beyond the age of 4 years. It is essential to immunize even those recovering from pertussis as natural disease does not offer complete protection.

For children *above 7 years of age*, the first dose should be of Tdap and subsequent doses of Td vaccine. This is followed by Td vaccine every 10 years. If Td is not available, then TT can be used. These children do not require Tdap vaccine dose at 10 years of age.

For adolescents/adults who have never received Tdap vaccine in past must be given single dose of the vaccine. Tdap can be given regardless of time elapsed since the last vaccine containing TT or diphtheria toxoid.

#### Pregnancy

Classically, TT vaccine has been recommended in pregnancy to protect the newborn from tetanus. For unimmunized pregnant woman, the first dose should be administered at the time of first contact/as early as possible and the second dose of TT should be administered 1 month later and at least 2 weeks before delivery. A single dose of TT would suffice for subsequent pregnancies that occur in the next 5 years; thereafter, 2 doses of TT would again be necessary. The WHO has recommended replacement of TT with Td in a phased manner.

Maternal immunization, particularly of pregnant women, may be an effective approach to protect very young infants and neonates from pertussis also. It has been shown that among several strategies to protect newborns/young infants from pertussis like immunization of pregnant women, postpartum immunization, cocooning and

neonatal immunization, immunization during pregnancy is possibly the best strategy today. Thus, in 2011, the Advisory Committee on Immunization Practices (ACIP) in USA recommended a dose of Tdap to all pregnant women after 20 weeks gestation to provide protection for both the mother and her newborn during the infant's earliest weeks of life. IAP, in its latest guidelines in November 2013 has also recommended immunization of pregnant women with a single dose of Tdap during the third trimester (preferred during 27–36 weeks gestation) regardless of number of years from prior Td or Tdap vaccination. Tdap has to be repeated in every pregnancy irrespective of the status of previous immunization (with Tdap). Even if an adolescent girl who had received Tdap 1 year prior to becoming pregnant will have to take it since there is rapid waning of immunity following pertussis immunization.

However, under UIP only TT vaccine is available as of now.

### Wound Management

All patients presenting with skin wounds/infections should be evaluated for tetanus prophylaxis. Cleaning of the wound, removal of devitalized tissue, irrigation and drainage is important to prevent anaerobic environment which is conducive to tetanus toxin production. The indications for TT and tetanus immunoglobulin (TIG) are given in **Table 1**. Again, replacement of TT with Td/Tdap is recommended.

**Table 1** Tetanus prophylaxis in wound management

	Doses of TT	Clean, minor wounds	All other wounds <sup>#</sup>	Given in past
	TT	TIG*	TT	TIG*
Unknown, < 3 doses, immunodeficient	Yes	Yes	Yes	Yes
≥ 3 doses	No**	No	No***	No

(Source: IAP Guidebook on Immunization, 2013–14.)

Abbreviations: TIG, tetanus immunoglobulin; TT, tetanus toxoid.

<sup>#</sup>Including, but not limited to, wounds contaminated with dirt, feces, soil, saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.

\*TIG: Tetanus immunoglobulin (250–500 IU IM)

\*\*Yes, if more than 10 years since last dose

\*\*\*Yes, if more than 5 years since last dose

### IN A NUTSHELL

1. The morbidity and mortality due to diphtheria, tetanus and pertussis has reduced significantly in India since introduction of the DTwP vaccines in EPI.
2. The overall coverage with primary and booster doses of the DTwP is still quite unsatisfactory.
3. Pertussis incidence is increasing in industrialized countries like US, Australia and many European countries using acellular pertussis vaccines in their national programs.
4. Immunity against all three components has been documented to wane over 6–12 years and hence regular boosting is recommended for all three antigens.
5. DTaP vaccines contain at least one of the separately purified antigens pertussis toxin (PT), filamentous hemagglutinin (FHA), pertactin (PRN), and fimbrial hemagglutinins 1, 2 and 3 (FIM type 2 and type 3), in addition to diphtheria and tetanus toxoids as in DTwP vaccines.
6. There is now consensus that aP vaccines are not as efficacious as wP vaccines in providing the *primary induction* and *durability of immune response* (faster waning).
7. The only advantage where aP vaccines score over wP is *safety*, i.e., less reactogenicity.
8. Multicomponent (> 3) aP vaccines are more effective than 1- and 2-component aP vaccines.
9. Most adverse effects of DTP are due to the pertussis component. The mild adverse effects are considerably low with DTaP vaccines than with DTwP vaccines. Serious adverse effects are a rarity even with DTwP vaccines.
10. Absolute contraindications to pertussis vaccination are history of anaphylaxis or development of encephalopathy within 7 days following previous DTP vaccination. These are applicable to DTaP vaccines too.
11. Only DTwP should be used in the primary series. DTaP vaccines may be preferred to DTwP vaccines only in children with history of severe adverse effects after previous dose/s of DTwP vaccines or with neurologic disorders.
12. For booster doses, DTaP can be considered, considering reactogenicity of DTwP vaccines. However, DTwP is preferable even in booster doses.
13. Whenever DTaP is chosen, the vaccine with at least 3 aP components should be chosen, the more the better.
14. Tdap vaccine is recommended at 10 years of age by IAP, followed by Td vaccine every 10 years (lifelong).
15. Maternal immunization, particularly of pregnant women, is an effective approach to protect very young infants and neonates from pertussis.

## Chapter 23.9

# Hepatitis B Vaccine

Ajay Kalra

Prevention of hepatitis B is aimed at preventing chronic carriage of the Hepatitis B virus. Though these carriers are often asymptomatic but are at an increased risk of developing cirrhosis and hepatocellular carcinoma. Carriers can also infect others over long periods of time. Further, chronic infection with hepatitis B virus (HBV) occurs in 80–90% of infants infected perinatally, in 30% of children infected before the age of 6 years; and in less than 5% of infections occurring in adults. Hence universal immunization with this vaccine is important and should begin at the earliest opportunity in life.

## THE VACCINE

The currently available vaccine which contains surface antigens of hepatitis B is a recombinant vaccine derived from the *Sacharomyces cervisiae* yeast and adjuvanted with aluminum salts and lipid A. Both thiomersol preserved and thiomersol free vaccines are available. The vaccines are available as single and multidose vials. They need to be stored at 2–8°C. The single pediatric dose vial of vaccine contains 10 µg of antigen and that for adult use contains 20 µg. Multidose vial contains 20 µg. Vaccines from different internationally reputed manufacturers are immunologically comparable and can be used interchangeably. The vaccine is available as monovalent formulation or in fixed combination with other vaccines such as diphtheria, pertussis (whooping cough), and tetanus (DPT) vaccine.

## Immunogenicity and Efficacy

Serum titers of anti-HBs (more than 10 mIU/mL) are considered as protective. This develops in 95–98% of healthy infants and children who receive a series of three intramuscular (IM) doses. In carefully conducted field trials, efficacy has been estimated to be up to 95%. The recommended series of three IM doses of hepatitis B induces a protective antibody response in more than 90% of healthy adults younger than 40 years of age. After the age of 40 years, the cumulative age-specific decline in immunogenicity drops to less than 90%, and by age 60 years, only 65–70% vaccines develop protective antibody level. Therefore, the earlier the vaccination starts, the better it is. Besides age, other factors, which decrease immunogenicity to hepatitis B vaccination, include obesity, smoking, presence of chronic disease and human immunodeficiency virus (HIV) infection, leukemia in whom the response is as poor as 20–40%. These patients need to be protected by hepatitis B immune globulin (HBIG) prophylaxis. Genetic non-responders and injection given in the gluteal region also elicit decreased immune response.

Some of the nonresponders will respond to doubling the dose like the immune compromised patients or to additional 1–3 doses. Genetic nonresponders will not respond to pure surface antigen vaccine and may respond to experimental vaccines containing preS1/preS2 antigen containing vaccines. Most of the old plasma derived hepatitis B vaccines contained some amount of preS1/preS2 antigens besides the hepatitis B surface antigen (HBsAg). Patients with chronic renal failure have been shown to respond to use of the vaccine along with cytokines like GCSF/GMCSE.

## Duration of Protection

Hepatitis B vaccine has been shown to induce long-term protection for 20 or more years. Although antibody level declines after 15–20 years of age, anamnestic reaction develops after a challenge with HBV and the person develops enough antibodies for protection. Therefore, booster doses are not routinely recommended.

## SCHEDULE OF ROUTINE VACCINATION

Hepatitis B vaccine can be given in any of the following schedules. Immunogenicity of the vaccine is not generally altered, provided at least 1 month interval between the two doses is adhered to.

- Birth, 1 and 6 months
- Birth, 6 and 14 weeks
- 6, 10 and 14 weeks [followed in Universal Immunization Program (UIP), India]
- Birth, 6 weeks, 6 months
- Birth, 6 weeks, 10 weeks, 14 weeks (followed in UIP, India for institutional births)

Three doses are recommended in all the schedules. The classical schedule is 0, 1 and 6 months. The dose is 10 µg for children less than 10 years and 20 µg for children above 10 years age or adults. Seroconversion rates are more than 90% after a three-dose schedule. Since seroconversion rates are lower in the elderly, the immunocompromised and those with renal failure, a four-dose schedule of 0, 1, 2 and 12 months of double dose is needed in these patients. While routine boosters are not needed in healthy children and adults, these may be needed in the immunocompromised children and those with chronic renal disease, whenever the anti HBsAg levels drop below the protective levels.

It is preferable to start vaccination within 12 hours of birth especially as routine antenatal screening for HBsAg is not practiced in India. Any schedule starting at 6 weeks age [tailored to be stitched with the other expanded program on immunization (EPI) vaccine starting at this age] carries the disadvantage of not preventing vertical transmission which is responsible for 18–40% of chronic cases in India. When used to conform to schedules for other childhood vaccines, the third dose should have a minimum gap of 8 weeks after the second dose and at least 16 weeks after the first dose. For infants, it should be at least 24 weeks of age.

The route of vaccination is intramuscular. The site of vaccination is anterolateral thigh in neonates and infants; deltoid in children and adults. Vaccination given by any other route than intramuscular or any other site than anterolateral part of thigh or deltoid should not be considered as valid. Intradermal administration of hepatitis B vaccine reduces the cost tremendously as the dose consists of 0.1 mL. But it has not been found to result in protective antibody titers in all recipients.

## Catch-up Vaccination

Catch-up vaccination with hepatitis B vaccine in a 0, 1, 6 months schedule should be offered to all children/adolescents who have not been previously vaccinated with hepatitis B vaccine. Prevacination screening with anti HBsAg antibody is not cost-effective and is not recommended. Catch-up vaccination is particularly important for contacts of HBsAg positive patient. Prevacination screening for HBsAg should be done in these contacts. If there is a gap of up to 6 months between the first and second dose or a gap of up to 1 year between second and third dose, there is no need to restart vaccination. Complete the remaining doses as per the original schedule. However, such delays are not desirable, as the person remains unprotected till the schedule is completed.

## Adolescent Vaccination

Routine hepatitis B vaccination is recommended for all children through age 18 years. All children not previously vaccinated with hepatitis B should be vaccinated at 11 years or 12 years age with 20 µg. The usual schedule for adolescents is 0–1–6 months. If an accelerated schedule is needed, the minimum interval between the second and third doses should be 8 weeks, but the first and third dose should be separated by at least 16 weeks.

## Reasons for Vaccine Failure

Improper storage of vaccine and failure to maintain cold chain are the most important causes of vaccine failure. Immuno-compromised individuals (those on chemotherapy etc.) may also fail to respond. Surface mutants of HBV may be able to cause infection even in vaccinated children. In addition, there are individuals who do not respond to the vaccine for no apparent reason. However, half of the people who do not develop anti-HBs antibodies after a three-dose series will do so after additional dose(s).

## Adverse Effects and Contraindications

Adverse effects of hepatitis B vaccine consist primarily of local reactions or low-grade fever. Serious reactions like anaphylaxis are very rare but can occur as with any other vaccine.

Persons with a history of serious adverse events, including anaphylaxis, after receipt of hepatitis B vaccine should not receive additional doses. As with other vaccines, vaccination of persons with moderate or severe acute illness, with or without fever, should be deferred until the illness improves. Vaccination is not contraindicated in persons with a history of multiple sclerosis, Guillain-Barré syndrome, or autoimmune diseases such as systemic lupus erythematosus or rheumatoid arthritis.

## Special Situations

### *Schedule for Immunocompromised Children*

These include advanced HIV infection, chronic renal failure, chronic liver disease, celiac disease and diabetes. It is estimated that 10% of the 40 million people infected HIV infection worldwide are coinfecting with HBV; the presence of HIV markedly increases the risk of developing HBV associated liver cirrhosis and hepatocellular carcinoma. This increase risk for developing chronic HBV may because of enhanced viral replication and ineffective immune clearance.

In immunocompromised hosts double the recommended dose for that age should be used. They may also require additional doses in case they do not show seroconversion following three doses. In situations where early seroconversion is required, one may use accelerated schedule of doses at 0, 1, 2 and 12 months. Despite this, it has been shown that not more than 30% of children with leukemia undergoing chemotherapy show seroconversion. In such cases, it may be better to use regular passive prophylaxis with HBIG. For hemodialysis patients the need for booster doses should be assessed by annual testing for antibody levels and booster doses should be provided when antibody levels decline below 10 mIU/mL.

### *Vaccination in Preterm and Low Birthweight Infants*

Preterm infants born to HBsAg positive women and women with unknown status must receive immunoprophylaxis with hepatitis B vaccine and HBIG beginning at shortly after birth. Preterm infants with birth weight less than 2,000 g have a decreased response to hepatitis B vaccine administered before 1 month of age. However, by chronological age 1 month, preterm infants, regardless of initial birth weight or gestational age, are likely to respond as adequately as full terms infants. Since the HBsAg status of most mothers is usually not known in our country, it is advisable to give the vaccine as recommended above within 12 hours. The next dose given at 1 month age will take care of the immunological incompetence if any of the preterm baby.

## Post-vaccination Testing

Routine post-vaccination testing for immunity is not necessary. It may be done in infants born to HBsAg positive mothers; chronic hemodialysis patients, children infected with HIV, immunocompromised patients, and those occupationally at risk. Testing should be done 1-2 months after administration of last

dose of vaccine using a method that allows for determination of a protective concentration of anti-HBs ( $\geq 10$  mIU/mL).

## HEPATITIS B VIRUS MUTANTS

As compared to other deoxyribonucleic acid (DNA) viruses, the HBV has a higher frequency of mutations. This is because the virus replicates via a ribonucleic acid (RNA) intermediate where the reverse transcriptase appears without a proof reading function. Mutations have been most well recognized in the pre-C/C gene, the polymerase gene and the pre S/S gene. While the Pre-C/C gene mutants are associated with fulminant hepatitis and severe chronic liver disease and the polymerase gene mutants with resistance to treatment with nucleoside analogs, the S gene mutants (surface mutants) are important from the vaccination point of view. The "a" domain containing 124-127 amino acids is major determinant of immune response. The HBV mutates at the 145 amino acid of the surface antigen, which is a very important site for the epitope and recognition by the anti-HBsAg antibody. These mutants might allow replication of HBV in the presence of vaccine induced anti-HBs or anti-HBs contained in the HBIG. Hence they are also called vaccine escape mutant. Also, these mutants may escape being detected in the blood bank testing. It is feared that high hepatitis B vaccination may lead to high level of surface mutant virus and replacement of the wild virus with the surface mutant virus may be in over a long period of time.

## HEPATITIS B IMMUNE GLOBULIN

Hepatitis B immune globulin provides immediate passive immunity and is recommended in situations where there has been acute exposure to HBsAg positive blood. HBIG does not interfere with the development of antibody response to hepatitis B vaccine and hence a person with accidental exposure should be given combined passive-active immunization. The dose in children is 32-48 IU/kg body weight. This should be administered within 7 days (preferably within 48 hours) of exposure. Postexposure prophylaxis with HBIG is recommended for newborn babies born to HBsAg positive mothers. 100-200 IU should be administered within 5 days (preferably within 24 hours). Another dose may be repeated after 2-3 months.

Postexposure prophylaxis with HBIG is also recommended for health personnel who suffer from accidental needle stick injury and for patients who receive HBsAg positive blood inadvertently. Pre-exposure passive prophylaxis with HBIG is needed for individuals failing to respond to vaccine (e.g., immunocompromised children), or in children with disorders that preclude a response (e.g., agammaglobulinemia), when they are likely to be exposed to the risk of acquiring HBV infection.

### *Postexposure Prophylaxis to Prevent Hepatitis B Infection*

*Prevention of perinatal HBV infection* In India where routine HBsAg screening is not possible, all infants born should be vaccinated within 12-24 hours of birth. In definitive situations where an infant is born to HBsAg positive mother, it should receive three doses of hepatitis B vaccines, first dose starting at birth (preferably within 12 hours) and then as per National guidelines. The baby also should receive HBIG 0.5 mL intramuscularly concurrently at different site along with the first dose at birth. In situations where HBIG could not be administered, hepatitis B vaccine alone has been found to be protective in over 90% cases. The cases are to be followed-up strictly for vaccination compliance and at 9-15 months of age anti-HBs and HBsAg titer should be determined. Infants found to be negative for anti-HBs should be revaccinated with complete schedule of three doses.

**Prevention in accidental percutaneous/permucosal exposure to blood** After a percutaneous (needle site, laceration, bite) or permucosal (ocular, mucous membrane) exposure to blood that contains or might contain HBV, obtain a blood sample from the source person to determine the HBsAg status. The vaccination and anti-HBs status of the exposed person is reviewed. **Table 1** depicts the postexposure prophylaxis regimen. The dose of HBIG is 0.06 mL/kg intramuscularly given as 1–2 doses.

## High-risk Approach vs. Universal Immunization Approach for Prevention of HBV Infection

Considering the high cost of vaccination, initially high-risk approach was followed. However, these failed to have any impact on the size of carrier pool in the population. Universal immunization targets every newborn, child and adult, thereby eliminating all modes of transmission. It also raises the possibility of ultimate eradication of this dreaded virus, as humans are the only reservoirs.

**Table 1** US Centers for Disease Control and Prevention (CDC) recommendations for postexposure prophylaxis against hepatitis B

Vaccination and antibody response status of exposed persons <sup>1</sup>	Treatment			
	Source is HBsAg positive	Source is HBsAg negative	Source is unknown or not tested	
			High-risk	Low-risk
Unvaccinated	HBIG <sup>2</sup> (1 dose) and begin a hepatitis B vaccine series	Begin a hepatitis B vaccine series	Begin a hepatitis B vaccine series	Begin a hepatitis B vaccine series
Known responder <sup>3</sup>	No treatment	No treatment	No treatment	No treatment
Not revaccinated	HBIG (1 dose) and begin a revaccination series	Begin a revaccination series	HBIG (1 dose) and begin a revaccination series	Begin a revaccination series B vaccine series
After revaccination <sup>4</sup>	HBIG (2 doses) <sup>5</sup>	No treatment	HBIG (2 doses) <sup>5</sup>	No treatment
Antibody response unknown	Test for anti-HBs <sup>6</sup> . If adequate <sup>3</sup> no treatment; if inadequate, HBIG x1 and vaccine booster	No treatment	Test for anti-HBs <sup>6</sup> ; If adequate <sup>3</sup> , no treatment, If inadequate, give vaccine booster and check anti-HBs in 1–2 months	

**Abbreviations:** HBsAg, hepatitis B surface antigen; HBIG, hepatitis B immune globulin.

**Note:**

1. Person known to have has HBV infection in the past or who are chronically infected do not require HBIG or vaccine.
2. Hepatitis B immune globulin (0.06 mL/kg) administered IM.
3. Adequate response is anti-HBs of at least 10 mIU/mL after vaccination.
4. Revaccination—additional three-dose series of hepatitis B vaccine administered after the primary series.
5. First dose as soon as possible after exposure and the second dose 1 month later.
6. Testing should be done as soon as possible after exposure.

**Source:** The table is adapted from "Updated US PHS Guidelines for the Management of Occupational Exposures to HBV, HCV, and HIV and Recommendations for Postexposure Prophylaxis." MMWR. 2001;50(RR-11):1-67.

## IN A NUTSHELL

1. Prevention of hepatitis B is necessary to prevent chronic carrier stage. Therefore, it should begin at the earliest opportunity of life, i.e., within 24 hours of birth.
2. Hepatitis B vaccine has been shown to give long-term protection for more than 20 years.
3. Booster doses are not recommended.
4. Different vaccination schedules have at least three doses, all having a comparable excellent immunogenicity.
5. The classical schedule is 0, 1 and 6 months giving seroconversion rate of more than 90%. The National Program of Immunization in India recommends three doses at 6, 10, 14 weeks with an additional zero dose at birth for institutional deliveries.
6. In immunocompromised hosts, the recommended dose is double the one for that age and an additional dose may also be required.
7. Adverse effects of the hepatitis B vaccine are very rare.

## Chapter 23.10

# *Haemophilus Influenzae*

## Type B (HIB) Vaccines

AK Patwari

*Haemophilus influenzae* type b (Hib), one of the six serotypes of capsulated *H. influenzae*, is an important invasive pathogen causing diseases such as meningitis, bacteremia, pneumonia, cellulitis, osteomyelitis, septic arthritis and epiglottitis. Most of the invasive Hib disease occurs in children in the first 2 years of life before natural protective immunity is acquired by the age of 3–4 years. Noncapsulated Hib disease causing bronchitis, otitis media, sinusitis and pneumonia is not amenable to prevention at present and can occur at all ages.

### HIB POLYSACCHARIDE VACCINE

*Haemophilus influenzae* type b capsular polysaccharide polyribosylribitol phosphate (PRP) was the first Hib vaccine to be developed. Earlier PRP vaccine studies demonstrated good immunogenicity in older children but limited immune response in young children. Efficacy studies suggested that the vaccine has waning protection over time and does not induce good immunological memory. The vaccine was introduced in United States as a single dose at 24 months in all children or at 18 months in children at high risk of invasive Hib disease. The vaccine was found to be safe, with few serious side effects. However, with the development of Hib conjugated vaccines, the use of Hib-PRP vaccine was discontinued.

### HIB CONJUGATE VACCINES

*Haemophilus influenzae* type b conjugate vaccines (Hib-CVs) have been developed during last two decades to improve the immune response in young children and to provide better memory response. These vaccines have conjugated PRP to diphtheria toxoid (PRP-D), the outer membrane protein group B *Neisseria meningitidis* (PRP-OMP), tetanus toxoid (PRP-T), and a nontoxic mutant diphtheria toxin (HbOC). HbOC and PRP-T vaccines show only a marginal increase in antibody levels after the first dose with a marked increase after the second dose and even better response after the third dose. On the other hand, PRP-OMP shows an increase in antibody level after the first dose itself with only marginal increases after the second and third doses. The onset of protection with PRP-OMP is thus faster. Additionally, while three doses of HbOC and PRP-T are recommended for primary vaccination, only two doses of PRP-OMP are recommended for this purpose. Hib-CV has been found to be highly immunogenic in Indian children.

### Immunogenicity

Efficacy trials have demonstrated 90–100% efficacy against culture proven invasive Hib disease for 1 year after vaccination. A trial in Gambian infants has shown 21% protection against episodes of severe pneumonia. The serologic correlate of protection at the time of exposure has been fixed at 0.15 µg/mL and that for long-term protection as 1 µg/mL. Even though immunological responses of these vaccines after each immunization have been reported to be variable in different population studies, the mean geometric concentration of anti-PRP antibodies in the children studied after three doses was greater than 1.0 µg/mL, the titer necessary for long-term protection, regardless of the formulation.

Indirect protection to the unimmunized susceptible children as a result of diminished Hib transmission (~50% of children exhibited anti-PRP titers  $\geq 5.0$  µg/mL; a level that impedes Hib upper respiratory carriage) has also been observed while conducting serological assessment of the Hib immunization program. Only HbOC and PRP-T are currently available in India. The vaccines should be stored at 2–8°C and the recommended dose is 0.5 mL intramuscularly.

### COMBINATION VACCINES

Over the years the combination of multiple vaccines into a single product has been a major advancement in improving compliance and protecting children from vaccine preventable diseases (VPDs). Hib vaccines have also been successfully produced as combination vaccines with diphtheria, tetanus, whole cell pertussis (DTwP) and hepatitis B (Hep B) antigen. These vaccines have been found to be as safe and effective as their noncombination counterparts. Side effects are mild and usually local.

### CURRENT STATUS OF HIB VACCINES

Developed countries where Hib vaccine was introduced for universal immunization have witnessed virtual elimination in Hib disease with no serotype replacement. The vaccine has also been shown to impart herd protection by reducing nasopharyngeal carriage. A notable exception in the Hib success story was an increased incidence of Hib disease in vaccinated children between the years 1999 and 2003 in the UK occurring after a remarkable initial decline in Hib disease in the early 1990s. Most of the cases of invasive Hib disease occurred in the late 2nd year of life. The major factor responsible for this phenomenon was omission of the 2nd year booster.

Hib vaccine induced immunity wanes overtime and reduced carriage of the organism in the environment compounds the problem by lack of natural boosting. It is also recognized now that immunological memory is insufficient for protection against Hib disease. Hence a booster dose is mandatory for sustained protection. Primary immunization with either pentavalent vaccine is reported to induce an excellent immunity lasting till the 2nd year of life. A booster dose with DTwP-Hib vaccine effectuated a good anamnestic response to all vaccine components, being especially strong for Hib in children previously vaccinated with pentavalent vaccine.

### Safety of Hib Vaccines

In India, after Hib vaccine was introduced in office practice of pediatricians for over a decade, 42% pediatricians ever observed any side effects or adverse event following immunization (AEFI). A meta-analysis of Hib combination vaccines found no increase in serious side effects when the Hib-combination vaccines was given as part of a combination or separately. However, a slight but significant increase in number of minor side effects like redness and pain at the injection site have been observed with combination vaccines as compared to separate vaccines. Based on the available data from Indian studies on vaccine safety, National Technical Advisory Group on Immunization (NTAGI) in India has concluded that the vaccine is safe and efficacious.

### RECOMMENDATIONS FOR USE

Hib-PRP conjugate vaccines are recommended as a separately administered vaccine or given as a part of combination vaccines to protect children from Hib disease. Different formulations of Hib-combination vaccines have been reported to have similar efficacy: HbOC (95–100%), PRP-OMP (95% in one study), PRP-T (88–100%). The only exception is PRP-D which has a wide variability in

efficacy ranging from 35% to 94% depending upon the population in which it was studied. Assessment of relative efficacy of one or the other Hib-combination vaccines and impact of any single vaccine has been difficult to ascertain because more than one Hib-combination vaccines has been used in many countries. However, the overall high reduction in the proportion of disease across countries suggests that the formulations of Hib vaccine currently in use provide excellent protection against invasive Hib disease.

The Government of India initially introduced pentavalent vaccine in the Universal Immunization Program (UIP) schedule in Tamil Nadu and Kerala and later on seven more states have included it in their immunization programs. It is hoped that with increasing awareness regarding the need for protection against Hib and safety of pentavalent vaccine other states will follow.

### Schedule and Doses

The vaccination schedule for Hib consists of three doses when initiated below 6 months, two doses between 6 months and 12 months and one dose between 12 months and 15 months, with a

booster at 18 months. For children aged more than 15 months a single dose may suffice. The interval between two doses should be at least 4 weeks. As Hib disease is essentially confined to infants and young children, catch-up vaccination is not recommended for healthy children above 5 years. However, the vaccine should be administered to all individuals with functional/anatomic hyposplenism irrespective of age.

Hib vaccines are now used mostly as combination vaccines with DTwP/DTaP/Hep B/IPV. Pentavalent vaccine introduced in India contains DTwP, Hep B and Hib, and is recommended to be given as per the schedule of DTP immunization in UIP. Indian Academy of Pediatrics (IAP) recommends three doses of Hib vaccine at 6, 10 and 14 weeks of age and a booster between 12 months and 18 months.

### Catch-up Vaccination for Hib Vaccines

When infants and children under-5 years of age have missed scheduled vaccine doses or start of Hib vaccination has been delayed, a catch-up schedule should be commenced (**Table 1**).

**Table 1** Recommended catch-up schedule when start of *Haemophilus influenzae* type b (Hib) vaccination has been delayed

Vaccine	Trade name	Age now			
		3–6 months	7–11 months	12–14 months	15–59 months
PRP-OMP <sup>1,2</sup> Hib (PRP-OMP)-hepB	PedvaxHIB Comvax	2 doses, 1–2 months apart and booster at 12 months	2 doses, 1–2 months apart and booster at least 2 months later, at 12–15 months	1 dose, and booster at least 2 months after previous dose <sup>4</sup>	Single dose <sup>3,4</sup>
HbOC <sup>3</sup> PRP-T <sup>3</sup>	HibTITER Hiberix ActHIB	3 doses, 2 months apart, and booster at 12 months	2 doses, 2 months apart, and booster at 12 months and at least 2 months after previous dose	1 dose, and booster at 18 months	Single dose <sup>3,4</sup>

<sup>1</sup> Extremely preterm babies (<28 weeks or <1,500 grams) who commence catch-up Hib vaccination with PRP-OMP between 3 months and 11 months of age require a 3-dose primary series (not 2 doses). The third dose should be given 1–2 months after the second dose of PRP-OMP. The booster dose should be given at 12 months as usual.

<sup>2</sup> Where possible, use the same brand of Hib vaccine throughout the primary course.

<sup>3</sup> When a booster is given after the age of 15 months, any of the 3 available conjugate Hib vaccines can be used.

<sup>4</sup> Depending on the combination used, further doses of hepatitis B or IPV are required.

Abbreviation: IPV, inactivated polio vaccine.

### IN A NUTSHELL

- Most of invasive Hib disease occurs in children in the first 2 years of life before natural protective immunity is acquired.
- H. influenzae*, causes many invasive diseases such as meningitis, bacteremia, pneumonia, cellulitis, osteomyelitis, septic arthritis and epiglottitis.
- In India, the burden of Hib disease is underestimated owing to lack of culture facilities, and difficulty to grow organism on usual culture media. Nevertheless, the burden is sufficiently high to warrant prevention by vaccination.
- Highly safe and efficacious Hib-conjugate vaccines, PRP-T and HbOC are available in India. Efficacy trials have demonstrated 90–100% efficacy against culture proven invasive Hib disease for 1 year after vaccination.
- Hib vaccines are also available as combination vaccines with diphtheria, tetanus, whole cell pertussis (DTwP), acellular pertussis (DTaP), IPV and hepatitis B (Hep B) antigen.
- Indian Academy of Pediatrics (IAP) recommends three doses of Hib vaccine at 6, 10 and 14 weeks of age and a booster between 12 months and 18 months. A booster dose of Hib vaccine is mandatory for sustained protection.
- Catch-up vaccination with Hib vaccine is recommended till 5 years of age.

## Chapter 23.11

# Measles Vaccine

Sumit Mehndiratta, AP Dubey

Measles vaccine is a part of Universal Immunization Program (UIP) of India. Most measles vaccines use the derivative of original strain (Edmonston) isolated in 1954 which include Schwartz, Edmonston-Zagreb, Edmonston-B, AIK-C and Moraten strains. Following measles vaccines are available: (1) monovalent measles vaccine; and (2) combination vaccines—measles containing vaccine (MCV): MR (measles, rubella), MMR (measles, mumps, rubella), MMRV (measles, mumps, rubella, varicella).

## ROUTINE IMMUNIZATION

Measles vaccine is a live attenuated vaccine with each dose (0.5 mL) containing at least 1,000 infective units (TCID<sub>50</sub>). It is available in a frozen state in single dose and multidose vials. The vaccine is administered subcutaneous/intramuscularly in upper arm/ anterolateral part of thigh. Strain used in India is usually formulated from Edmonston-Zagreb strain grown on human diploid cells or purified chick embryo cells. The vaccine is to be reconstituted with the diluent provided. It is kept at 2–8°C and away from light. It has to be used within 4–6 hours of reconstitution as it does not contain any preservatives. Hence, there are chances of bacterial contamination (*Staphylococcus*) and development of toxic shock syndrome (TSS) due to its exotoxin.

As per National immunization schedule, the measles vaccine (MCV) is administered at 9 months or 270 completed days. But in case of an outbreak, as per Indian Academy of Pediatrics (IAP) recommendation, the vaccine can be administered to children aged 6–11 months. However, these children should be revaccinated with two doses of MCVs, the first at ages 12–15 months and at least 4 weeks after the previous dose, and the second at ages 4–6 years.

## Vaccine Failure

Primary vaccine failure rate is around 15%. Therefore, a second dose of measles vaccine is recommended by National Technical Advisory Group on Immunization (NTAGI). Secondary vaccine failure is rare.

## Contraindications

Severe immunocompromised conditions; past history of severe allergic reaction to vaccine; and pregnancy.

## Adverse Reactions

Mild pain and tenderness at injection site; fever (>103°F in 5–15% recipients between 7th and 12th day); febrile seizures; transient rash (in 5% recipients between 7th and 10th day and lasts 1–3 days); thrombocytopenic purpura; depression of cell mediated immunity; rarely anaphylactic reactions (1 case per 3.5 million doses); encephalitis (1 case per million doses); and toxic shock syndrome (TSS) due to staphylococcal contamination.

## Immune Responses

The vaccine induces both humoral and cellular immune response just like the natural infection. Measles virus-specific antibodies and the circulation of measles virus-specific CD4+ and CD8+ T lymphocytes confer protection against disease. Due to interference from passively transmitted antibodies from mother, the rates differ according to age. It is around 80–85% when administered at 9 months of age. The antibodies develop in around 98% cases of children immunized at 15 months of age. The immunity

is long lasting. The immunogenicity of vaccine is lower in immunocompromised states.

## Second Dose of Measles Containing Vaccine

In India, the overall vaccine coverage is around 70%. Assuming 85% effectiveness, there is buildup of substantial number of susceptible children over a period of time. With an annual birth cohort of 26 million children in India, every 2–3 years the population of susceptible children reaches epidemic threshold. Thus the rationality for providing second opportunity for measles vaccination is two-fold. Firstly, it will cover the primary vaccine failures, and secondly, it will cover those children who missed the first dose of routine immunization. The NTAGI has recommended the implementation strategy of second dose of measles containing vaccine (MCV2) at the state level on the basis of the underlying performance of the routine immunization (RI) program.

In total, 14 states with measles coverage less than 80% (Arunachal Pradesh, Assam, Bihar, Chhattisgarh, Gujarat, Haryana, Jharkhand, Madhya Pradesh, Manipur, Meghalaya, Nagaland, Rajasthan, Tripura and Uttar Pradesh) will introduce MCV2 through catch-up vaccination campaigns. In the remaining 21 states with better performing routine immunization systems (i.e., 80% routine measles coverage), 17 states will introduce MCV2 for children aged 16–24 months through the routine program. The remaining four states and union territories (Delhi, Goa, Puducherry and Sikkim) already use a second dose of measles vaccine in their RI program (as mumps-measles-rubella vaccine) financed with state resources.

## IMMUNIZATION IN SPECIAL CIRCUMSTANCES

- *Asymptomatic human immunodeficiency virus (HIV) infected children:* Yes (at 9 months age).
- *Symptomatic HIV infected children:* Yes (at 9 months age if CD4 count >15%).
- *Patients who have received corticosteroids—prednisolone 2 mg/kg/day or its equivalent for more than 14 days should not be administered measles vaccine for 1 month.*
- *Children with congenital immunodeficiency:* Vaccine can be given but will be ineffective due to concomitant immunoglobulin therapy.
- *The children with severe egg allergy* can be safely given Measles vaccine.
- *The children who had received antibody containing products* like whole blood, packed red cells, plasma, and immunoglobulin should not be given live attenuated vaccines and these products should be avoided for at least 2 weeks after receipt of these vaccines.

## IAP RECOMMENDATIONS ON MEASLES VACCINATION

- The first dose of vaccine is to be administered at 9 months (270 days) completed age.
- In view of the fact that around 15% cases of primary vaccine failure, an additional dose of MCV preferably MMR should be administered at 15 months age.
- The second dose of MMR (third dose of MCV) at 4–6 years of age, just before school entry. The second dose of MMR can be given at any time 4–8 weeks after the first dose.
- Catch-up vaccination beyond 12 months should be with MMR. Recent (2014) recommendations of IAP have substituted stand-alone measles vaccine with MMR at 9 months. The MCV2 would also be MMR at 15 months. The second dose of MMR at 4–6 years of age has been scrapped. This revision is influenced by Government of India's proposal to introduce MR vaccine at 9 and 16–24 months of age in its UIP schedule.

## PASSIVE IMMUNIZATION

Infants are protected by transplacental transfer of maternal antibodies up to 6 months of age, but in some cases the immunity may persist for 9 months. Measles immunoglobulin (Human) can be administered to prevent measles but it is only effective when administered in early incubation period (within 6 days of exposure). The recommended dose is 0.25 mL/kg (0.5 mL/kg in immunocompromised subjects). Maximum dose is 15 mL. It can be used for prevention of disease in infants and immunodeficient contacts of acute cases.

## GLOBAL MEASLES AND RUBELLA INITIATIVE

Measles vaccination coverage has been selected as an indicator of progress towards achieving Millennium Development Goal 4 (MDG-4 goal). It is a joint effort of WHO, United Nations Children's Fund (UNICEF), the American Red Cross, the United States Centers for Disease Control and Prevention, and the United Nations Foundation to support countries to achieve measles and rubella control goals. Since the year 2000, with support from this effort over 1 billion children all over the world have been reached through mass vaccination campaigns. The goals of this initiative are that by the end of 2015, global measles death to be reduced by 95% as compared to 2000 levels. Further, by 2020, the goal is to achieve measles and rubella elimination in at least five WHO regions.

WHO recommends that every child receive two doses of measles vaccine. The World Health Assembly in the year 2010 established three milestones towards the future eradication of measles, to be achieved by the year 2015:

- Increase routine coverage with the first dose of measles-containing vaccine (MCV1) for children aged 1 year to more than or equal to 90% nationally and more than or equal to 80% in every district or equivalent administrative unit;
- Reduce and maintain annual measles incidence to less than 5 cases per million; and
- Reduce estimated measles mortality by more than 95% from the 2000 estimate.

[online] From: [http://www.who.int/immunization/newsroom/Measles\\_Rubella\\_StrategicPlan\\_2012\\_2020.pdf](http://www.who.int/immunization/newsroom/Measles_Rubella_StrategicPlan_2012_2020.pdf). Accessed November 3, 2014.

WHO. Measles vaccines: WHO Position paper. *WER*. 2009;84:349-60.

### IN A NUTSHELL

1. Measles contributes to about 4% of under-5 child mortality in India, and around 80,000 children die every year.
2. Routine measles vaccinations along with mass immunization campaigns are key public health strategies to reduce global measles deaths.
3. Measles vaccination resulted in a 78% drop in measles deaths between 2000 and 2012 worldwide.
4. Safe and effective measles vaccines are available as *stand-alone* and *combination vaccine* formulations.
5. Two doses of measles or measles containing vaccine are needed for effective control.
6. Measles can be eliminated globally with judicious use of vaccine.
7. The key objectives of Global Measles and Rubella Initiative are to achieve measles and rubella elimination in at least five WHO regions by year 2020.

## Chapter 23.12

# Rubella and Mumps Vaccines

Aashima Dabas, Piyush Gupta

### RUBELLA VACCINES

Rubella was first identified as a distinct exanthematous illness in 1964–65. The burden and impact of this illness was better understood after recognition of congenital rubella syndrome (CRS) which is characterized by congenital heart defects, hearing loss, cataracts/glaucoma, microcephaly, jaundice and hepatosplenomegaly. Countries from the developed world have recorded significant decline in incidence of CRS from 4 to 8 per 10,000 pregnancies to less than 0.01 per 10,000 pregnancies following rubella vaccine use. The developing countries account for most of burden of CRS with incidence of CRS in India varying from 1% to 15% as per hospital based data; hence the need for vaccination.

### Immunization against Rubella

#### Passive Immunization

The hyperimmune rubella immunoglobulin (Ig) was prepared in the past but is currently not available for use. Pooled Ig may be used instead in pregnant women exposed to rubella. It may modify the disease severity but does not reduce the risk of CRS and is thus no longer advocated.

#### Active Immunization

The rubella vaccine was first developed for use in 1969. The rubella vaccine was initially manufactured using the animal tissue culture cell lines. The current vaccine (RA 27/3) is a live attenuated vaccine derived from human diploid fibroblasts which was licensed for human use since 1979. It is to be reconstituted with distilled water and administered subcutaneously. The vaccine is available as monovalent form (Rubella only) or as a combination like measles-rubella (MR), measles-mumps-rubella (MMR) or measles-mumps-rubella-varicella (MMRV).

#### Immunogenicity

A single dose of vaccine results in good seroconversion reported as high as 95–100% after 4–8 weeks of vaccine administration.

#### Mucosal and Cellular Immune Response

The vaccine induces mucosal and cellular protective responses. Both IgM and IgG protective antibodies are demonstrable after 21–28 days post-vaccination. In addition, specific secretory IgA is also expressed in the nasopharynx which is implicated in providing protection from reinfection. The cellular responses like induction of lymphoblast proliferation also have some plausible role to play.

#### Age Specifications/Schedule

There are two age and host choices for vaccine administration—adolescent girls (to reduce CRS burden) or early childhood. India alone has a large pool (10–35%) of adolescent girls who are seronegative and susceptible to rubella. This susceptibility increases in a rural setting. The National Technical Advisory group on Immunization (NTAGI) thus recommended rubella vaccine to all adolescent girls 10–19 years in their report in 2010. However, by immunizing only adolescent girls, the chain of transmission remains undisrupted, thus the need for administering the vaccine in early childhood also. In 2014, a subcommittee of NTAGI

recommended introduction of rubella vaccine as bivalent MR vaccine into the Universal Immunization Program (UIP). The MR vaccine will replace measles at 9 months and second dose of the same combination will be given along with second booster of diphtheria, pertussis (whooping cough), and tetanus (DPT) vaccine at 16–24 months of age.

The seroconversion was reported to be as high as 96–99% after vaccine administration in 9–18 months age. The epidemiological studies later showed persistence of protective antibodies in 99% of recipients by 4–5 years age which dropped to 65–74% by adolescence. Therefore a single dose of rubella vaccine in early childhood failed to suffice protection during adolescence against CRS.

#### Duration of Immunity

A single dose administered after infancy provides adequate protection till 5 years age. Around 10% vaccinees are prone for reinfection after 5 years and thus a second dose is required at that age. The immunity after two doses is presumed lifelong.

#### Safety

The vaccine is a relatively safe vaccine with minimal local side-effects. It is contraindicated in those with history of anaphylaxis to vaccine component. The rare systemic side-effects include arthropathy and thrombocytopenia. Vaccine induced arthropathy is a rare occurrence in children. It was reported among adult recipients but lacked virological proof for causation or association. Thrombocytopenia may occur in 1:22,300 doses but is less severe than that resulting from natural infection. The second dose of vaccine should be administered with caution in any child who reported thrombocytopenia with an earlier dose. The earlier associations of rubella vaccine with Guillain-Barré syndrome, autism, ulcerative colitis and aseptic meningitis have been refuted. The US Centers for Disease Control and Prevention (CDC) now declares rubella as a safe vaccine. The vaccine should not be administered during pregnancy. Pregnancy should be delayed by 1 month after vaccination. Inadvertent vaccine administration during pregnancy does not warrant abortion. It should be avoided in immunocompromised children but may be given to an asymptomatic HIV positive child.

### Public Health Perspectives

A standing technical subcommittee (STSC) of NTAGI reviewed the overall burden of rubella and CRS in India and offered new recommendations which include:

- Introduction of rubella vaccine as MR vaccine in place of measles vaccine at 9 months of age and second dose at the time of first DPT booster at 16–24 months of age in states having achieved more than 80% coverage of first dose of measles vaccine;
- A onetime catch-up campaign of adolescent girls with rubella vaccine to offset potential increase in susceptible women in reproductive age group if children alone are vaccinated; and
- Sentinel surveillance for CRS to be included in MR surveillance program.

The rubella vaccine is part of the state health programs currently in Delhi, Goa, Puducherry and Sikkim whereas Kerala introduced rubella vaccine in 2014 as MMR. The vaccine is offered during second year of life and has reported low coverage rates as 42%, 30% and 5% from Delhi, Chandigarh and Goa, respectively. Globally, the launch of *Measles and Rubella Initiative* and new strategic plan to eliminate both the diseases by 2020 has shifted global focus on rubella and CRS. However, Southeast Asia including India was one of the last regions and countries to commit these goals. By 2012, 132 out of 194 World Health Organization (WHO) member states have introduced *rubella containing vaccine (RCV)* in their National

immunization programs, either as MR or MMR. Of these, 117 have RCV included in both routinely administered doses of measles-containing vaccine.

In addition to routine immunization services, there exists a need to maintain a surveillance system to track CRS incidence. A worldwide system LabNet has been established under WHO to monitor for both measles and rubella. India is also making efforts to setup a similar home surveillance network.

### Recommendations for Use

The Indian Academy of Pediatrics (IAP) recommendations state two doses of MMR as RCV at 9 and 15 months. There are many studies documenting efficacy of MMR vaccine when given before 12 months of age even in India. The Government of India has recently introduced rubella vaccination as MR vaccine substituting measles at 9 months and second dose along with second DPT booster at 16–24 months of age in areas with more than 80% vaccination coverage.

### MUMPS VACCINE

Mumps is a viral illness which frequently results in school and work absenteeism. In symptomatic individuals, it is characterized by parotitis (in 60–70%), epididymo-orchitis, meningitis, or rarely as other organ involvement. The burden of mumps is largely under-reported due to subclinical nature of the disease. The secondary attack rate among household contacts is high (31%). In Maharashtra, India around 60% of children less than 2 years of age were susceptible to illness as per 2007 data. Moreover, incidence rates have dropped by 98% and outbreaks have decreased in countries like United States since routine implementation of mumps vaccine. Considering the cost:benefit ratio of routine immunization to losses incurred by the economy due to disease morbidity, mumps vaccine seems a reasonable choice for all children.

### Immunization against Mumps

#### Passive Immunization

Immunoglobulins are not indicated in mumps as the defense is primarily by cellular immunity. Specific mumps Ig are no longer available.

#### Active Immunization

The vaccine is a live attenuated vaccine manufactured by either of the following strains—Leningrad-Zagreb (L-Zagreb), Leningrad 3, Urabe, Rubini and Jeryl-Lynn. All of them have shown comparable immunogenicity profile with varying safety concerns (discussed later). The current vaccine available for use in India uses the L-Zagreb and Jeryl-Lynn strain and is available as trivalent (measles-mumps-rubella). An earlier produced monovalent mumps vaccine has been withdrawn from US and UK and the quadrivalent (measles-mumps-rubella-varicella) is not yet available in India. The vaccine is to be reconstituted with distilled water and administered subcutaneously at dose of 0.5 mL.

#### Immunogenicity

The immunogenicity of various strains varies from 63% to 96% for Jeryl-Lynn and 84% to 95% for Urabe or L-Zagreb strains. The failure rate among vaccinees varies from 5.4% to 8.8% irrespective of the strain on vaccine.

#### Mucosal and Immune Responses

The vaccine induces a robust cellular response among recipients. The vaccine also results in herd immunity (approximately 90%) if used with high vaccine coverage (85–90%).

### Age Specifications/Schedule

Though the minimum age of offering the vaccine is after infancy to minimize the interaction of maternal antibodies, there are studies where mumps vaccine was successfully administered with good seroconversion at 9 months of age. High seroconversion rates (95–100%) were achieved at 10–15 months age in Indian children as per different studies; similar to western data. The seroconversion rates decline with increasing age to 93% in 5–6 years and 86% in 9–10 years age.

### Duration of Immunity

Since introduction of mumps vaccine in 1977, the prevalence of mumps had decreased by more than 98% by 1985 indicating robust primary response of the vaccine. The effectiveness of single dose vaccine is approximately 80%. A resurgence of cases was reported in 1989 among vaccinated school going children in the US. This suggested for recommending a second dose of mumps at 5–6 years age. The effectiveness of two dose vaccine ranges from 88% to 95% as per different studies. However, in 2006, an outbreak was reported among young adults (18–24 years age) in US who had received second dose of mumps almost 10 years earlier. People who were exposed to wild virus infections demonstrated natural boosting and higher protective antibodies. It was suggested that the asymptomatic transmission had chiefly accounted for the outbreak. Also a different serotype was causative for the outbreak than the mumps-vaccine-derived serotype, inferring lesser heterologous cross-protection with mumps vaccine.

### Safety

The most frequent side effects associated with the vaccine are mild fever, transient rash like illness and local site pain or redness. Allergic reactions in few susceptible individuals allergic to egg protein can occur. Parotitis or aseptic meningitis has been reported rarely after vaccination using the L-Zagreb or Urabe strain. Recently, there are reports on increased risk of febrile seizures with MMRV vaccine. The vaccine is best avoided in pregnancy and in symptomatic immune-compromised individuals but can be given in asymptomatic HIV children.

### Public Health Perspectives

The prevalence of mumps related encephalitis has decreased dramatically in post-vaccine era. The vaccine is in routine use in developed countries. In India, both limited routine immunization coverage and additional costs for mumps vaccine dissuaded the implementation of mumps vaccine in routine immunization. However, considering the economic benefits after reduction in work absenteeism in post-mumps vaccination phase, mumps vaccination seems a feasible and cost-effective measure in areas which have more than 80% vaccination coverage.

### Recommendations for Use

The vaccine is still not a part of National immunization schedule in India. The CDCs advisory committee on immunization practices (ACIP) and IAP advisory committee on vaccines and immunization practices (IAP-ACVIP) recommends two doses of mumps vaccine (given as combination MMR). The vaccine is a part of adult vaccination in few countries (like Scotland) and can be given in certain high-risk adults like international travelers, health-care workers, those visiting international universities or during outbreaks.

### IN A NUTSHELL

1. A highly effective live attenuated vaccine (RA 27/3) against rubella is available having close to 100% efficacy.
2. Government of India has decided to launch rubella vaccine as a bivalent measles-rubella (MR) vaccine into UIP. The MR vaccine will replace measles at 9 months and second dose of the same combination will be given along with second booster of DPT vaccine at 16–24 months of age.
3. Safe and reasonably effective live attenuated mumps vaccine is also available.
4. At least two doses of mumps vaccine are needed to have good protection.
5. Different strains of mumps virus are utilized in the production of mumps vaccine which is available as trivalent MMR vaccine.
6. The mumps vaccine has not yet been included in UIP of India though few states are offering this vaccine in their mass immunization programs.
7. The Indian Academy of Pediatrics has argued strongly in favor of inclusion of mumps into UIP in place of MR vaccine.

## Chapter 23.13

# Typhoid Fever Vaccines

Sushant Sahastrabudde,  
Mohammad Imran Khan

Typhoid fever, an acute febrile illness that is often fatal, remains an important public health problem globally; especially in the developing countries in Asia and Africa (**Fig. 1**). It causes 220,000 to 600,000 deaths and 16 to 22 million illnesses per year, predominantly in children of school-age or younger in the developing world. Improvement in water supply, hygiene and sanitation infrastructure have resulted in reduction of typhoid fever incidence in most developed countries. Though the same path must be followed for the countries that still suffer from typhoid, it may take a few decades for these countries to provide safe and hygienic environment. Given this fact, it is essential to consider a comprehensive approach that combines targeted vaccination of high-risk populations as a short- to medium-term measure, combined with the longer term solutions of water and sanitation improvements and elevated living standards.

## INACTIVATED WHOLE-CELL VACCINES

Heat-inactivated phenol-preserved whole-cell typhoid vaccines have been available since the 1890s. The vaccine was moderately efficacious (51–88%) in children and young adults in preventing typhoid fever, and the protection persisted for up to 7 years. However, their high levels of reactogenicity; fever (up to 30% of the vaccines), headache (up to 10%), and severe local pain (up to 35%), led to their removal from public health programs in most countries.

## NEW-GENERATION VACCINES

Two new-generation vaccines have been available in the market since late 1980s to early 1990s: the oral live attenuated Ty21a and injectable Vi polysaccharide vaccine (**Table 1**).

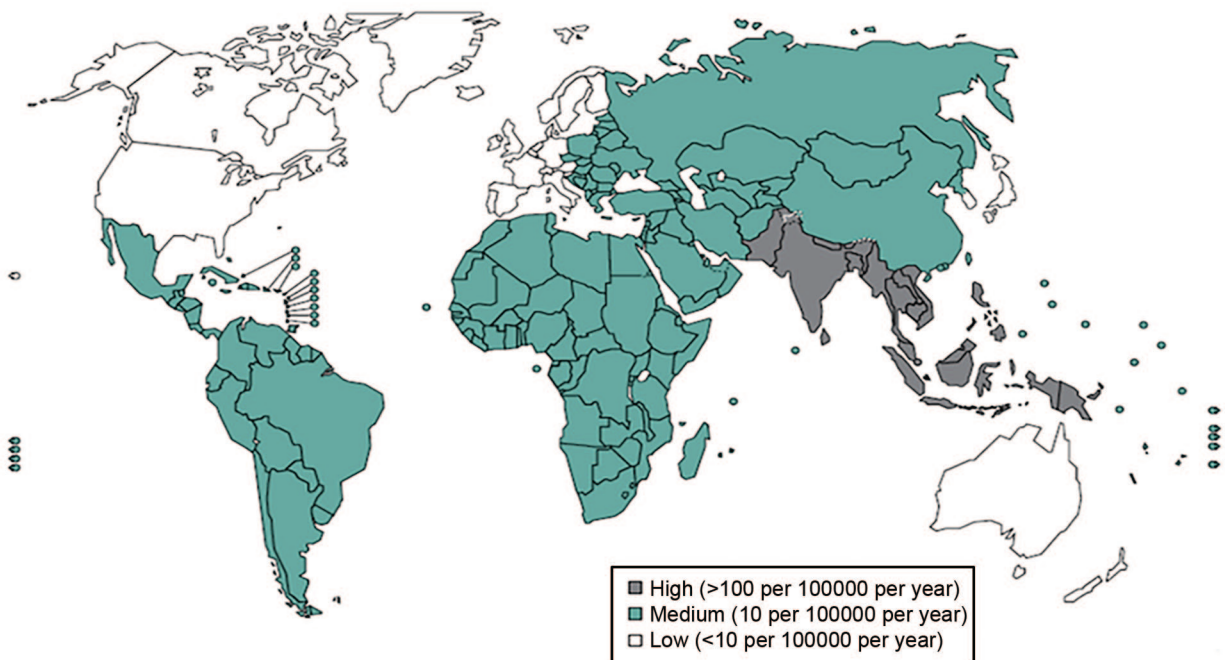

### Live, Oral Ty21a Vaccine

The Ty21a vaccine consists of a mutant strain of *Salmonella typhi* Ty2 which was isolated after chemical mutagenesis and has a galE- and Vi-negative phenotype. Immune response to the vaccine starts 14 days after vaccination, which is mediated by mucosal (IgA), serum (IgG), and cell-mediated antibodies. The overall protective efficacy for a three-dose regimen ranged between 67% and 80% in large-scale efficacy trials, conducted in 1980s in Chile. It is reported that the vaccine also protects against infection from *S. paratyphi B*. A recent study reported that the vaccine induces humoral response against *S. paratyphi A*, though no clinical protection has been studied. The most common adverse events reported with Ty21a were mild and transient gastrointestinal disturbances, followed by general symptoms such as fever. This vaccine is licensed for use in persons 2 years and above for the liquid formulation and 5 years and older for the capsule formulation, although the liquid formulation is currently unavailable. This vaccine is not available in Indian market now.

### Parenteral Vi Polysaccharide Vaccine

This subunit vaccine was developed from wild type *S. typhi* strain Ty2 on the basis of non-denatured purification of the Vi polysaccharide. The injectable Vi polysaccharide vaccine is given in a single dose and was found to confer, overall, 64–72% protection for 17–21 months and 55% over 3 years. Vi polysaccharide vaccine is well tolerated and safe. In a recent cluster-randomized effectiveness trial, the vaccine has also shown an evidence of herd protection. The most common side effects are pain, redness and

Geographical distribution of typhoid fever

**Figure 1** Country-specific incidence rates of typhoid fever

(Figure source: Crump JA, Luby SP, Mintz ED. The global burden of typhoid fever. Bull WHO 2004;82:346-53. The map showing country-specific incidence rates for the year 2000)

**Table 1** Characteristics of the two new-generation typhoid fever vaccines; Ty21a and Vi polysaccharide

Characteristic	Live attenuated Ty21a	Vi capsular polysaccharide
Vaccine type	Live attenuated	Subunit
Composition	Chemically-mutated Ty2 strain of <i>S. typhi</i>	Purified Vi capsular polysaccharide of the Ty2 <i>S. typhi</i> strain
Immunogenic properties	<ul style="list-style-type: none"> <li>Elicits mucosal IgA and serum IgG antibodies against O, H and other antigens, as well as cell-mediated responses</li> <li>No booster effect has been shown</li> </ul>	<ul style="list-style-type: none"> <li>Elicits serum IgG Vi antibodies</li> <li>T-cell independent (no booster response)</li> </ul>
Route of administration	Oral	Parenteral (subcutaneous or intramuscular)
Minimum age vaccine is licensed for use	2 years old for liquid formulation and 5 years old for capsule formulation	2 years old
Formulation	<ul style="list-style-type: none"> <li>Enteric-coated capsules, or</li> <li>Liquid suspension (lyophilized vaccine + buffer mixed with water upon use)</li> </ul>	<ul style="list-style-type: none"> <li>Solution of 25 µg combined with buffer</li> </ul>
Number of doses required for complete vaccine regimen	Three to four	One
Storage requirements	Requires storage at 2–8°C	Requires storage at 2–8°C
Shelf life in higher temperature	14 days at 25°C	6 months at 37°C 2 years at 22°C
Safety/tolerability	High	High
Efficacy at 3 years (95% CI)	51% (36%, 62%)	55% (30%, 70%)
Length of protection	At least 5–7 years	At least 3 years

induration at injection site, and fever. In very rare cases, allergic reactions and rashes have been observed. Vi is not immunogenic in children less than 2 years of age. The vaccine is used in the private market in India, but not yet included in Universal Immunization Program for mass vaccination.

### Limitations of Current Vaccines and Newer Vaccine Candidates in Development

The currently available typhoid vaccines, although effective, have many limitations which have contributed to their limited uptake by the public sector globally. Both the available vaccines are modestly immunogenic, cannot be given to children less than 2 years of age, and are costly. Additionally, Ty21a is currently only available in capsule format that can be administered in children 5 years and above, requires multiple doses, and has to be maintained in strict cold chain. Vi polysaccharide requires repeated dosing every 3 years and because it is polysaccharide capsule-based, is T-cell independent. In view of these inadequacies, there have been many efforts in the recent past to improve upon the existing licensed vaccines.

#### Improvements in the Live Oral Vaccines

Several live oral typhoid vaccine candidates are currently under development. By utilizing recombinant DNA technology future live attenuated typhoid vaccines can become increasingly immunogenic, perhaps to the point of inducing protective immunity with only a single dose of vaccine. Some of the candidates in the pipeline are: Strain Ty800 with a mutation in *phoP/phoQ*, CVD 908-htrA, CVD 909, and M01ZH09.

#### Improvements in the Vi Polysaccharide Vaccine

Several aspects of Vi typhoid polysaccharide vaccines are similar to those of other polysaccharide bacterial vaccines such as Hib, pneumococcal and meningococcal C vaccines. The most important common feature is that all polysaccharide vaccines cannot produce immunological memory so they fail to induce anamnestic response

(*T-cell independent immunity*). These polysaccharide-based bacterial vaccines have shown that they cannot elicit sufficient immune responses in young children or infants. As shown in the precedents of other bacterial polysaccharide conjugate vaccines, typhoid vaccines can potentially overcome these issues associated with polysaccharide alone by a conjugation technology. Methods have been devised, therefore, to synthesize Vi protein conjugates in order to both enhance the antibody response and confer T-dependent properties to the Vi and theoretically increase its protective action in populations at high-risk for typhoid fever.

#### Vi-rEPA Prototype Typhoid Conjugate Vaccine

The scientists at the US National Institute of Child Health and Disease (NICHD) have developed a technique to bind Vi to a nontoxic recombinant carrier protein that is antigenically identical to *Pseudomonas aeruginosa* exotoxin A. The resultant conjugates (Vi-rEPA) were more immunogenic in mice and juvenile rhesus monkeys than the Vi alone. Conjugates of this polysaccharide with several medically relevant proteins induced booster responses also. The safety and immunogenicity of this vaccine candidate was evaluated in 2–5-year-old children in Vietnam. None of the recipients experienced fever or significant local reactions. The over-all efficacy after 27 months of active surveillance followed by 19 months of passive surveillance was 89%. In a randomized, vaccine controlled study of infants in Vietnam, Vi-rEPA was safe, elicited protective levels of IgG anti-Vi and was compatible with Expanded Programme on Immunization (EPI) vaccines.

### Typhoid Conjugate Vaccines in Development

#### Vi-polysaccharide-TT Conjugate Typhoid Vaccine (PedaTyph® by Biomed Pvt Ltd., India)

Biomed Pvt Ltd. in India developed a conjugate vaccine using tetanus toxoid as the carrier protein with 5 µg of Vi-polysaccharide. This product was tested in a clinical trial in 169 subjects more than 12 weeks with a comparison group (Vi) of 37 children more than

2 years. A fourfold or greater rise in antibody titer of each group was reported which was statistically equivalent to Vi-rEPA. The vaccine was licensed for use in children older than more than 3 months of age in 2008 in India as two doses injections of 0.5 mL each at interval of 4–8 weeks in 3 months to 2 years old children; followed by booster at 2 years and 2.5 years of age; and as two injections at interval of 4–8 weeks in children older than 2 years of age. Booster vaccination is recommended every 10 years thereafter.

### *Vi-Polysaccharide-TT Conjugate Typhoid Vaccine (Typbar-TCV<sup>®</sup> by Bharat Biotech)*

Bharat Biotech in Hyderabad, India also developed a typhoid conjugate vaccine using tetanus toxoid as the carrier protein with Vi-polysaccharide. This vaccine was tested in children (2–17 years) for safety, immunogenicity and dose ranging (15 µg versus 25 µg/0.5 mL). There was no significant difference in immune response between two doses of 25 µg/0.5 mL and two doses of 15 µg/0.5 mL. In the second clinical trial, comparative assessment of the immunogenicity of Vi-TT versus the polysaccharide vaccine was done in 981 participants (6 months to 45 years old). There was a 4-fold rise in the seroconversion in each treatment arm of Vi-TT at 6 weeks postvaccination. This vaccine is now licensed in India for a single dose indication above 9 months of age and is available as Typbar-TCV<sup>TM</sup>.

### *Vi-Polysaccharide-CRM197 Conjugate Typhoid Vaccine by Novartis Vaccines*

The Novartis Vaccines Institute for Global Health (NVIGH), Siena, Italy, has developed a typhoid conjugate vaccine (Vi-CRM197) using Vi from *Citrobacter freundii* WR7011 conjugated to the, CRM197, a nontoxic mutant of diphtheria toxin. Phase II studies have also been completed in India, Pakistan, and Philippines in four different age-groups: 18–45 years; 24–59 months; 9–12 months; and infants aged 6 weeks with each group having 40 subjects. The vaccine was found to be safe and immunogenic, but the lack of booster response and reduction in antibody titers after 6 months has thrown many questions about this candidate.

### *Vi-Polysaccharide-Diphtheria Toxoid (DT) Conjugate Typhoid Vaccine by IVI, Korea*

The International Vaccine Institute (IVI) based in Seoul, Korea also started the work on Vi-DT typhoid conjugate vaccine: Vi from *S. typhi* strain from India (C6524) conjugated to diphtheria toxoid as the carrier protein. The technology was then transferred to Shantha Biotechnics in India in 2009; PT Bio farma in Indonesia and SK Chemicals in Korea in 2013. Shantha Biotechnics since then has completed the preclinical studies and have produced the clinical trial batches.

### *Other Candidates*

Finlay Institute in Cuba is also developing a typhoid conjugate vaccine and has plans to replace the Vi-polysaccharide vaccine in their immunization programs with a typhoid conjugate vaccine.

## IAP RECOMMENDATIONS FOR TYPHOID VACCINES

**Primary schedule** According to new recommendations, typhoid conjugate vaccine is to be administered for primary immunization at 9–12 months of age. There are currently two typhoid conjugate vaccines, Typbar-TCV<sup>®</sup> and PedaTyph<sup>®</sup> available and licensed in the country. However, as of now this recommendation is applicable to the former only. Only a single dose of the vaccine is recommended for primary series, however, an interval of at least 4 weeks with the measles vaccine is recommended.

**Boosters** Those who received a dose of Typbar-TCV<sup>®</sup> at 9–12 months they can be prescribed booster of either Vi-polysaccharide (Vi-PS) or the Typbar-TCV<sup>®</sup> vaccine at 2 years of age. However, Vi-PS vaccine recipients would need revaccination every 3 years till the intended duration of protection.

## PUBLIC HEALTH PERSPECTIVES

Despite the slow progress, some countries and local governments have begun to consider typhoid vaccine for their public health programs. In the South Asian region, following publication of the updated WHO position paper, countries participating in a 2009 WHO South East Asia Regional Office (SEARO) prioritization workshop classified typhoid vaccination as an *immediate* priority. The Sri Lankan Ministry of Health has recently planned for the use of typhoid vaccines in high burden populations. The National Committee on Immunization Practices (NCIP) of Nepal has recommended the use of typhoid vaccines for disease control in the Kathmandu valley. The Indian Academy of Pediatrics Advisory Committee on Vaccines and Immunization Practices (IAP ACVIP) has recommended the immediate inclusion of typhoid ViPS vaccines in the national immunization schedule. Typhoid vaccines are also recommended by the Indonesian Pediatric Association. Considering the heterogeneity of disease burden and antibiotics resistance at inter- and intra-country level, the WHO 2007 position paper on typhoid vaccine suggests the use of typhoid vaccines in high-risk population and in high endemic areas. Typhoid endemic countries are urged to review their disease burden data to identify the high-risk age groups and to introduce the vaccination program in conjunction with other measures, such as improvement in water and sanitation, provision of health education, and training of health-care workers for proper treatment and diagnosis.

### IN A NUTSHELL

1. Inactivated whole-cell vaccines though moderately effective against typhoid fever are no longer in use owing to high incidence of reactogenicity.
2. Two new-generation vaccines, the oral live attenuated Ty21a and injectable Vi-polysaccharide (Vi-PS) vaccine are currently available globally.
3. Vi-PS vaccine despite modest efficacy is the most commonly used vaccine in private sector in India whereas oral Ty21a is no longer available in Indian market.
4. Limitations of current Vi-PS vaccines like ineffectiveness below 2 years, need of repeated boosters and modest protection led to development of several Vi-PS-protein conjugate vaccines.
5. Two Vi-PS-protein conjugate vaccines are already licensed in India and few are in the pipeline.
6. Typhoid vaccination is not a part of Universal Immunization Program (UIP) in India despite high endemicity.
7. WHO has suggested the use of typhoid vaccines in high-risk population and in high endemic areas.

## Chapter 23.14

# Japanese Encephalitis Vaccine

VG Ramachandran

Japanese encephalitis (JE) vaccines first became available in the 1950s. Inactivated mouse brain derived vaccine using Nakayama strain of the virus and/or Beijing-1 strain was the first to be used. Its production stopped in 2005. Inactivated vaccine after cultivation in primary hamster kidney cells of the Beijing-3 strain was the second JE vaccine. Beijing 3 is the main variant of the vaccine strain used in China from 1968 to 2005. Central Research Institute, Kasauli, Himachal Pradesh used to produce the mouse brain vaccine but not any longer. Similarly, primary hamster kidney cell grown inactivated vaccine has also ceased production. Following new, second generation JE vaccines are available now:

- Live attenuated, cell culture-derived SA14-14-2 JE vaccine
- Inactivated SA14-14-2 vaccine (IC51) (IXIARO by Intercell and JEEV® by Biological Evans India Ltd.
- Inactivated vero cell culture-derived Kolar strain, 821564XY, JE vaccine (JENVAC® by Bharat Biotech)
- Chimeric vaccine (IMOJEV by Sanofi Pasteur)
- Inactivated vero-cell derived JE vaccine (Beijing-1 JE strain by Biken and Kaketsuken, Japan).

### LIVE ATTENUATED, CELL CULTURE-DERIVED SA14-14-2 JAPANESE ENCEPHALITIS VACCINE

This vaccine is based on the genetically stable, neuro-attenuated SA14-14-2 strain of the JE virus, which elicits broad immunity against heterologous JE viruses. Reversion to neurovirulence is highly unlikely. The live attenuated vaccine was licensed in China in 1989. Since then, more than 300 million doses have been produced and more than 200 million children have been vaccinated. Extensive use of this and other vaccines has significantly contributed to reducing the burden of JE in China from 2.5/100,000 in 1990 to less than 0.5/100,000 in 2004. This vaccine is also licensed for use in Nepal (since 1999); South Korea (since 2001); India (since 2006); Thailand (since 2007) and Sri Lanka.

**Dosage and route of administration** In China, the vaccine is licensed for 0.5 mL dose to be administered subcutaneously to children at 8 months of age and a second opportunity again at 2 years. In some areas, a booster dose is given at 7 years. It should not be used as an outbreak response vaccine. It can also be offered to all susceptible children up to 15 years as catch-up vaccination.

**Immunogenicity** After a single dose, antibody responses are produced in 85–100% of nonimmune 1–12-year-old children. A neutralization antibody titer of more than 1:10 is generally accepted as evidence of protection and post-vaccination seroconversion.

**Safety** The vaccine has an excellent safety profile.

**Efficacy** Case control studies and numerous large-scale field trials in China have consistently shown an efficacy of at least 95% following two doses administered at an interval of 1 year. In a field trial in Nepal in 1999, involving more than 160,000 subjects 1–15 years of age, reported efficacy of a single dose of 99.3% in the same year and 98.5% 1 year later. At 5 years the protective efficacy was 96.2%. Vaccine in this study contained  $10^{5.8}$  PFU/0.5 mL. However, data from postmarketing surveillance (PMS) in India showed that protective efficacy of the vaccine in India is not as high as that seen in Nepal. Achievement of a sustained reduction in JE in areas where many children received only a single dose of SA14-14-2 vaccine, suggests that the efficacy of this vaccine exceeds the ability to detect a circulating neutralizing antibody response to a single administered dose.

**Recommendations for use** Both Government of India and Indian Academy of Pediatrics have now recommended a second dose of the vaccine to provide more complete and sustained protection. First dose of the vaccine can be administered at 9 months along with measles vaccine and second at 16–18 months at the time of first booster of DTP vaccine.

### INACTIVATED SA14-14-2 VACCINE (IC51) (IXIARO BY INTERCELL AND JEEV® BY BIOLOGICAL E. INDIA LTD

IC51 is a purified formalin inactivated whole virus vaccine licensed in US, Australia and Europe during 2009 derived from the attenuated SA14-14-2 Japanese encephalitis virus (JEV) strain propagated in Vero cells. It has been evaluated in several clinical studies in adults and children in India and in several other countries. This vaccine has now been approved by US FDA and EU for use in children from the age of 2 months onwards. Each 0.5 mL liquid formulation in a ready-to use prefilled syringe contains approximately 6 µg of purified, inactivated JEV proteins and 0.1% aluminum hydroxide as an adjuvant.

**Dosage and schedule** 0.25 mL dose for children 2 months through 2 years of age, and 0.5 mL dose for children more than or equal to 3 years of age and adults. Primary series involves two doses administered 28 days apart.

**Immunogenicity** There is no efficacy data for JE-VC (IXIARO®), and the vaccine has been licensed in pediatric age group especially for travelers to Asian countries on the basis of a phase III randomized controlled trial (RCT) conducted amongst 1,867 subjects in the Philippines, and favorable interim data from a second phase III trial in EU, US and Australia. In both studies, the JE vaccine was shown to be highly immunogenic in children or adolescents aged 2 months to less than 18 years with a safety profile comparable to pediatric vaccines licensed for other diseases. A phase II trial from India investigated the safety and immunogenicity of JE-VC in healthy children aged 1 and 2 years in India, using a standard (6 µg) or half (3 µg) dose. Seroconversion was achieved in more than 90% of recipients. Exact duration of protective neutralizing antibodies in the serum is not known; however a boosting effect is demonstrated by repeat dose.

**Safety** The safety profile of JE-VC vaccine is similar to the JE-MB vaccines. However, it is less reactogenic, showed a higher potency, a higher persistency, and patient convenience (two instead of three doses: at 0 and 28 days) than mouse brain vaccines.

**JEEV-the Indian variant of IC51, IXIARO** A vaccine for endemic markets based on Intercell's technology was launched in 2012 under the trade name JEEV® in India. In 2011, BE Ltd. India conducted a multicentric open label randomized controlled phase II/study to evaluate safety and immunogenicity of JEEV® vaccine in almost 450 children ( $\geq 1$  to  $< 3$ -year-old) and compared to control Korean Green Cross Mouse Brain Inactivated (KGCC) vaccine. This study demonstrated seroconversion (SCR) of 56.28% on day 28 and 92.42% on day 56 in BE-JE (JEEV®) vaccinated group. JEEV® has been licensed by drug authorities in India for use in prevention of JE virus infection in children and adult.

**Recommendations for use** According to IAP, the vaccination against JE is not recommended for routine use, but only for individuals living in endemic areas. The Academy recommends a primary schedule of 2 doses of 0.25 mL for children aged between  $\geq 1$  and  $\leq 3$  years and 2 doses of 0.5 mL for children more than 3 years, adolescents and adults administered intramuscularly on days 0 and 28. However, the long-term persistence of protective efficacy and need of boosters are still undetermined.

## INACTIVATED VERO CELL CULTURE-DERIVED KOLAR STRAIN, 821564XY, JE VACCINE (JENVAC® BY BHARAT BIOTECH)

In the year 2013, Bharat Biotech International, a Hyderabad based firm obtained marketing and authorization rights from Drugs Controller General of India (DCGI), India for a JE vaccine after phase II or phase III trials, which showed good safety and seroprotection even after single dose administration. The vaccine is marketed as JENVAC® in Indian market is a Vero cell-derived purified, inactivated product that is said to be applicable to all age groups and also during epidemics. The seed strain is an indigenous JE isolate from Kolar, Karnataka, by NIV, Pune.

**Immunogenicity** A single dose of the test vaccine was sufficient to elicit good immune response. At 28th day, the subjects who had received a single dose were 98.67% seroprotected and 93.14% seroconverted (fourfold) for  $\leq 50\text{--}\geq 1$  years, whereas the corresponding figures for the reference vaccine were 77.56% and 57.69%, respectively. The seroconversion (93.14% and 96.90%) and seroprotection (98.67% and 99.78%) percentages on the 28th and 56th day were not significantly different and similarly, no statistically significant difference in these rates was noted amongst different age groups.

**Safety** The vaccine showed excellent safety during Indian trial. There was no serious adverse event (AE) or AE of any special interest noted in the study. None of the enrolled subjects were withdrawn from the study for vaccine related adverse reaction. AES were reported significantly lower after second dose, when compared to after first dose of test vaccination. The AES reported after second dose in test group were not significantly different than the AES reported after placebo administration as second dose in reference group.

**Recommendations for use** According to IAP recommendations, two doses of the vaccine (0.5 mL each) administered intramuscularly at 4 weeks interval for the primary immunization series starting from 1 year of age. A booster is needed at later stage; however the exact timing of the booster along with feasibility of single dose for primary series can be determined only after obtaining the long-term follow-up data.

## CHIMERIC VACCINE (IMOJEV BY SANOFI PASTEUR)

YF-JE is live attenuated and commercially available as IMOJEV. Licensed in Australia in August, 2010 and in Thailand in December, 2012, it is given in two intramuscular doses on day 0 and day 28. The vaccine strain is derived by insertion of nucleic acid sequences encoding envelope proteins for prM and E of the SA14-14-2 strain of JE into the yellow fever 17D backbone, lacking in neurotropic properties. Immunogenicity of IMOJEV is not affected by concomitant measles-mumps-rubella (MMR) administration. This vaccine is contraindicated in pregnancy. Also, a vaccinee should avoid pregnancy until 28 days post-vaccination. The trial of this vaccine is yet to be completed in India.

## INACTIVATED VERO-CELL DERIVED JE VACCINE (BEIJING-1 JE STRAIN)

The Osaka University, Biken, has produced Biken BK-VJE a vero-based vaccine formulated in alum and using the Beijing-1 JE strain. Kaketsuken, one of the Japanese producers of mouse brain-derived JE vaccines has produced a purified non-adjuvanted vero cell-derived vaccine formulated without gelatin or thimerosal. Phase III trials have demonstrated production of neutralizing antibody in 100% of subjects. These vaccines are not available in India.

## JAPANESE ENCEPHALITIS VACCINATION FOR TRAVELERS

Japan, South Korea, North Korea, Taiwan, Vietnam, Thailand and China practice routine childhood immunization against JE. Travel associated JE can occur in people of any age but risk is based on destination, duration, season and activities of the traveler. Risk of disease among travelers in Asia is 1 in 10,00,000. Susceptibility does not decrease with mass immunization. Vaccination in travelers will depend on the prevalence of disease in the area and type of exposure during travel. In area of no risk vaccination is not required. Increasing incidence of disease has been reported from Asia. Usually endemic disease is not noted and epidemics are detected late hence vaccination should be recommended for selected travelers to Asia who are at high-risk (outdoor activity and during epidemics), those who are to stay for more than 30 days. Travel high-risk areas include, India, Nepal, Myanmar, Sri Lanka, China, Cambodia, Korea, Laos, Malaysia, Philippines, Thailand, Vietnam. JE vaccine is not suitable for children below 1 year.

### IN A NUTSHELL

1. Japanese encephalitis (JE), mainly affects children aged 1–15 years. About 50,000 cases occur annually with 15,000 deaths and a case fatality rate ranging from 5% to 35%.
2. Most infections are asymptomatic with a population dependent variable symptote: asymptote ratio of 1:25 to 1:1000.
3. The survivors of JE are left with crippling neurological sequelae in as much as 50% of patients.
4. JE is widely prevalent in many parts of India with states like eastern UP, West Bengal, Assam, Bihar and some North-East states are badly affected.
5. Mass immunization, control of mosquito vectors, prevention of mosquito from biting humans, control or protection of reservoirs, changes in pig husbandry, and reduction in land utilized for rice cultivation are some key interventions needed to control JE.
6. Conventionally available *inactivated mouse brain derived JE vaccine* using Nakayama strain of the virus is no longer available in use.
7. Cost, efficacy and safety concerns led to the development of a number of new JE vaccines, many of which are licensed and available for use in the country.

## Chapter 23.15

# Rabies Vaccines

Anuradha Bose

The currently available vaccines in India are the modern cell culture vaccines (CCV) and include purified chick embryo cell vaccine (PCECV), human diploid cell vaccine (HDCV), purified vero cell vaccine (PVRV), purified duck embryo vaccine (PDEV) (**Table 1**). The production of nerve tissue vaccine (NTV) was stopped in India in 2004. These vaccines are available in lyophilized form with sterile water as diluent, are stable for 3 years at 2–8°C and should be used within 8 hours of reconstitution. Rabies vaccines contain more than 2.5 IU of antigen per intramuscular dose, with a diluent of 1.0 mL, or 0.5 mL depending on the product. The entire dose should be given intramuscularly regardless of the age or weight of the patient.

**Table 1** Rabies vaccines available in India

1.	Abhayrab	Purified vero cell rabies vaccines (PVRV)	Human biological
2.	Indirab	Chromatographically purified (PVRV)	Bharat Biotech International Ltd., Hyderabad
3.	Rabipur	Purified chick embryo cell vaccine (PCECV)	Novartis
4.	Rabivax	Human diploid cell vaccine	Serum Institute of India
5.	Verorab	Vero cell	Ranbaxy
6.	Verovax-R	Vero cell (monkey kidney cells)	Sanofi Aventis
7.	Vaxirab	Purified duck embryo cell vaccine	Zydus Healthcare Ltd., Ahmedabad
8.	Vaxirab N	Purified chick embryo cell vaccine (PCECV)	Zydus Healthcare Ltd., Ahmedabad

**Table 2** Rabies immunoglobulins available in India

Serial No	Type of Immunoglobulin	Name	Company	Strength
1.	Equine	Anti-rabies serum (ARS)	Central Research Institute, Kasauli	5 mL vial (300 IU/mL)
2.	Equine	Equirab	Bharat Serums and Vaccines, Mumbai	5 mL vial (300 IU/mL)
3.	Equine	Vinrig	VINS Biopharma, Hyderabad	5 mL vial (300 IU/mL)
4.	Equine	AbhayRig	Human Biologicals Institute, Hyderabad	5 mL vial (300 IU/mL)
5.	Human	Berirab-P	Bharat Serums and Vaccines, Mumbai	150 IU/mL; 2 mL (300 IU) 5 mL (750 IU) ampoules
6.	Human	ImogenRab	Sanofi Pasteur	150 IU/mL; 2 mL (300 IU) 5 mL (750 IU) ampoules
7.	Human	KamRab	Kamada Ltd. Israel/Synergy Diagnostics	150 IU/mL; 2 mL (300 IU) 5 mL (750 IU) ampoule

**Site of injection** The deltoid is the preferred site for the intramuscular injections, and the anterolateral aspect of the thigh in infants and young children. The gluteal region should not be used as it is believed that the fat in this region retards the absorption of the antigen.

**Antibody levels** These vaccines induce protective antibodies in more than 99% of vaccinees following pre exposure prophylaxis or postexposure prophylaxis (PEP). An antibody titer of 0.5 IU is considered protective.

**Adverse effects** The main adverse effects are local pain, swelling and redness and less commonly fever, headache, dizziness and gastrointestinal side effects. Systemic hypersensitivity reactions in vaccinees have been reported with HDCV particularly following booster injections. Intradermal vaccination may cause more local irritation than intramuscular.

### RABIES IMMUNOGLOBULIN

Rabies immunoglobulin (RIG) contains specific anti-rabies antibodies that neutralize the rabies virus. There are two types of RIG:

1. Human rabies immunoglobulin (HRIG)—dose is 20 U/kg body weight, maximum dose 1,500 IU.
2. Equine rabies immunoglobulin (ERIG)—dose is 40 U/kg body weight, maximum dose 3,000 IU.

Human rabies immunoglobulin is preferred, but is expensive. The currently available ERIG preparations (**Table 2**) are potent, safe, highly purified and less expensive as compared to HRIG and can be used if the HRIG is not accessible. There is a small risk of anaphylaxis and any administration of RIG should be done only with the full resuscitation kit available nearby. The World Health Organization (WHO) does not recommend skin testing prior to ERIG administration as they do not accurately predict anaphylaxis risk.

Rabies immunoglobulin is indicated in all cases of category III wounds (**Box 1**), and category II exposure in the immunocompromised. RIG is not indicated in individuals who have received pre-exposure prophylaxis or PEP in the past. RIG should be infiltrated thoroughly into and around the wound, diluting the RIG with saline if the area to be infiltrated is large. The remaining part if any is to be injected IM. Adverse reactions include tenderness

or stiffness at the injection site, low grade fever. The RIG should be administered as early as possible but no later than the seventh day after the first dose of vaccine was given, as the antibody response to the vaccine is presumed to occur from day 8 onwards.

## GENERAL PRINCIPLES

In a rabies endemic country like India, every bite should be considered as potentially infective. The factors to be considered while deciding treatment are:

- The *category of exposure* (**Box 1**).
- The *vaccination status of the animal* A history of vaccination of the animal is not evidence that the animal is protected. In case of bites by pet animals, PEP may be deferred only if the pet responsible for exposure is more than a year old, has a vaccination certificate indicating that it has received at least two doses of a potent vaccine, the first not earlier than 3 months of age and the second within 6–12 months of the first dose and in the past 1 year. Bites by puppies are potentially dangerous as they are too young to have been immunized and even very young pups have been known to transmit rabies.
- *Observation of the animal involved* The animal should ideally be kept under observation. The conventional observation period of 10 days is valid only for dogs and cats. If the animal cannot be observed, as in the case of a stray, or if the animal has been killed the animal is best considered as potentially rabid. If the animal remains well through the 10-day period,

the PEP can be converted to a pre-exposure prophylaxis, by omitting the day 14 dose and giving the day 28 dose of the Essen schedule. Full PEP should be started urgently if there are signs of illness in the pet.

- *The animal* PEP is indicated following exposure to the saliva of any warm blooded animal. These include dogs, cats, cows, buffaloes, sheep, goats, pigs, donkeys, horses, camels, foxes, jackals, monkeys, mongoose, bears and others. Rabies due to bats, and rodent bites has not been reported in India. Wild animal bites are considered as category III.
- *Special circumstances* Extremes of age, (infancy and old age), pregnancy, lactation, concurrent illness are not contraindications for rabies PEP. Patients who may be immunocompromised for any reason should be offered immunoglobulin even for category II exposure.
- *Timing of treatment* Prophylaxis should be given as soon as possible. It should not be denied or deemed unnecessary however late after exposure the patient presents. Even wound cleansing should be done at first contact, however late the patient presents, if there is a wound with a break in the skin.

## POSTEXPOSURE PROPHYLAXIS

All categories II and III bites merit rabies vaccine. PEP when administered strictly according to protocol (**Table 3**) protects against development of rabies.

### The Wound

The first step is thorough cleansing of the wound with soap and flushing under running water for 10 min. This should be followed by irrigation with a virucidal agent such as 70% alcohol or povidone iodine. Antimicrobials and tetanus toxoid should be given if indicated. Where indicated, RIG should be infiltrated into the wound. Any suturing of wound should be avoided. When suturing is unavoidable for purpose of hemostasis, it must be ensured that RIG has been infiltrated in the wound prior to suturing.

### Schedule

The standard schedule (Essen protocol) is five doses on days 0, 3, 7, 14 and 28, with day '0' being the day of commencement of vaccination. Dose is 1 mL intramuscular. (Some vaccines have 0.5 mL diluent only; dose is then 0.5 mL). The same product should be used for the course. Interchange of vaccines should be avoided. For

### BOX 1 Categories of rabies exposure

Rabies exposure is categorized into three and use of antirabies biological products depends on the category of exposure. All categories need to be washed and wound management done.

*Category I:* Touching, feeding of animals or licks on intact skin—*no exposure and if history is reliable: no treatment.*

*Category II:* Minor scratches or abrasions without bleeding or licks on broken skin and nibbling of uncovered skin: *use vaccine alone.*  
*Use immunoglobulin + vaccine if patient is immunocompromised.*

*\*Category III:* Single or multiple transdermal bites, abrasions that bleed, scratches or contamination of mucous membrane with saliva (i.e., licks) *Use immunoglobulin + vaccine.*

*Any bite from a wild animal is considered a category III bite.*

**Table 3** Rabies postexposure prophylaxis (PEP) schedule

Vaccination status	Intervention	Regimen*
Not previously vaccinated	Wound cleansing	All PEP should begin with immediate thorough cleansing of all wounds as described earlier
	Human rabies immunoglobulin (HRIG)	Administer 20 IU/kg body weight. Infiltration into the wound and remainder at an anatomical site (intramuscular [IM]) distant from vaccine administration. HRIG should not be administered in the same syringe as vaccine
	Vaccine	Human diploid cell vaccine (HDCV) or purified chick embryo cell vaccine (PCECV) 1.0 mL, IM (deltoid area†) or purified vero cell vaccine (PVRV), 1 each on days 0, 3, 7, 14 and 28 (5 doses)
Previously vaccinated**	Wound cleansing	Immediate thorough cleansing of all wounds
	HRIG	HRIG should not be administered
	Vaccine	HDCV or PCECV 1.0 mL, IM (deltoid area†), 1 each on days 0 and 3

\*These regimens are applicable for persons in all age groups, including children.

†The deltoid area or for younger children, the outer aspect of the thigh may be used. Vaccine should never be administered in the gluteal area.

\*\*The PEP recommendation of 2 doses, one each on days 0 and 3, is applicable regardless of time elapsed between the previous vaccination and the current exposure.

minor deviations from the schedule, vaccination can be resumed with the same intervals between doses as though the patient were on schedule. For example, if day 7 is missed and patient reappears on day 10, then the days are: 10, 17, and 31. The dose is the same at all ages and weights.

### Other Schedules

- **Zagreb schedule** is a reduced multisite intramuscular regimen (2-1-1): four doses distributed in three visits on days 0, 7 and 21. This is an alternative 4 day schedule, if an accelerated response is considered necessary: Two doses are given on day 0 in the deltoid muscle, right and left arm. Subsequent doses, one each on day 7 and day 21. This schedule is not recommended in India.
- **Reduced 4-dose schedule** (Not recommended by IAP). Dose 1 mL intramuscular on days 0, 3, 7, 14. The day 28 dose is omitted. The rationale for this is based on reviews of series of fatal cases, where most deaths occurred before day 28, and none of them could be attributed to a failure to receive the fifth (day 28) vaccine dose.
- **Intradermal schedules** Intradermal vaccination helps reduce costs. The dose required is only 0.1 mL. This volume should contain 0.25 IU of antigen.
  - **Thai Red Cross Regimen:** 2-2-2-0-1-1, two intradermal (ID) doses on the deltoid on days 0, 3, 7 and 1 dose on day 30 and 90.
  - **Updated Thai Red Cross Regimen:** 2-2-2-0-2-0, (ID) two doses on days 0, 3, 7 and 30.
  - **Eight Site Regimen: (Not approved in India):** 8-0-4-0-1-1, 8 intradermal doses on each upper arm, each lateral lower abdominal quadrant, each thigh and each suprascapular regions on day 0. Four doses are given on day 7 on each thigh and upper arm and one dose on day 30 and 90 on upper arm.
- **Re-exposure schedule** There are studies to show that good antibody levels persist up to 10 years. However, on account of the nature of the disease, for re-exposure at any point of time after completed (and documented) preexposure prophylaxis or PEP, two doses are given, one each on days 0 and 3.

### PRE-EXPOSURE PROPHYLAXIS

Where the exposure may be unrecognized (laboratory personnel) or unreported (children), preexposure prophylaxis may be considered. It has the advantage of eliminating the need for RIG. It also reduces the PEP to two doses only. Pre-exposure prophylaxis is recommended for certain high-risk groups (**Box 2**).

#### BOX 2 Indications for rabies pre-exposure prophylaxis

1. **Continuous exposure:** Laboratory personnel in research and industry.
2. **Frequent exposure:** Veterinarians, laboratory personnel involved with rabies diagnosis, doctors and allied staff treating rabies patients, dog catchers, zoo keepers, forest staff. Children who may be exposed to stray dog menace and pet owners.
3. **Infrequent exposure:** Postmen, courier boys, travelers (backpackers) to rabies endemic countries.

### Dosage

Three doses are given intramuscular on days 0, 7 and 28 (day 21 may be used if time is limited, e.g., as with imminent travel) but day 28 is the better option. The intradermal schedule has been shown to be effective for pre-exposure prophylaxis, but is not approved in India for this purpose.

### Assessment of Antirabies Antibodies Titers

Routine assessment of antibody titers is not recommended unless the person is immunocompromised. The highly exposed persons should check antibody titers every 6–12 months and have a booster dose of the vaccine if antibody levels fall below 0.5 IU/mL. When serologic testing is not available booster vaccination every 5 years is an acceptable alternative.

### IN A NUTSHELL

1. In a rabies endemic country like India, every bite should be considered as potentially infective. A history of vaccination of the animal is not evidence that the animal is protected.
2. Bites by puppies are potentially dangerous as they are too young to have been immunized.
3. The use of older *nerve tissue vaccine* (NTV) was stopped in India in 2004.
4. The new generation, currently available vaccines in India are the modern cell culture vaccines (CCV) and include purified chick embryo cell vaccine (PCECV), human diploid cell vaccine (HDCV), purified vero cell vaccine (PVRV), purified duck embryo vaccine (PDEV).
5. The deltoid and anterolateral aspect of the thigh (in infants and young children) are the preferred site for the intramuscular injections. The gluteal region should not be used.
6. The available rabies vaccines are highly efficacious and induce protective antibodies in more than 99% of vaccines following pre-exposure prophylaxis or postexposure prophylaxis.
7. Rabies immunoglobulin (RIG) is indicated in all cases of category III wounds, and category II exposure in the immunocompromised.
8. The currently available equine rabies immunoglobulin (ERIG) preparations are potent, safe, highly purified and less expensive than human RIG. There is no need of skin testing prior to ERIG administration.
9. For *postexposure prophylaxis* five doses are recommended on days 0, 3, 7, 14 and 30, with day '0' being the day of commencement of vaccination.
10. For re-exposure at any point of time after completed (and documented) pre-exposure prophylaxis or PEP, two doses are given, one each on days 0 and 3.
11. Pre-exposure prophylaxis involves three doses given IM on days 0, 7 and 28.

## Chapter 23.16

# Pneumococcal Vaccines

Puneet Kumar, Vipin M Vashishtha

Two types of vaccines are currently licensed against pneumococcus (*Streptococcus pneumoniae*): Pneumococcal polysaccharide vaccine (PPSV) and pneumococcal conjugate vaccines (PCVs). While PPSV offers *broad-based, add-on* protection, despite its limitations, to children who are at high-risk to contract pneumococcal disease (PD), PCVs have much greater public health importance as they *effectively* prevent *pneumococcal pneumonia*, one of the leading killers of under-5 children. This chapter would briefly discuss both of these vaccines, with special emphasis on current Indian scenario.

### PNEUMOCOCCAL POLYSACCHARIDE VACCINE

The first pneumococcal vaccine was developed as early as 1945. It was a tetravalent vaccine containing 30–60 µg each of capsular polysaccharide antigens of four serotypes (1, 2, 5 and 7), but was not widely distributed since its deployment coincided with the discovery of penicillin. In 1970s, Robert Austrian succeeded in developing 14-valent PPSV that was licensed in 1977. This finally evolved into 23-valent vaccine that was first licensed in 1983.

Currently available PPSV is a 23-valent vaccine containing purified capsular polysaccharide antigens (25 µg each) of the 23 serotypes of pneumococcus that were responsible for over 95% of cases of invasive disease in US and other developed countries *before* the introduction of PCV in routine vaccination. These serotypes are: 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19F, 19A, 20, 22F, 23F and 33F. The vaccine does not contain any adjuvant. Being a polysaccharide vaccine, it is T-cell independent vaccine and thus is poorly immunogenic below the age of 2 years, has low immune memory, and lacks *booster effect* with repeated doses. It also does not reduce nasopharyngeal carriage and does not provide herd immunity.

#### Immunogenicity

A single dose of PPSV23 results in the induction of serotype-specific antibody response. Although being a polysaccharide vaccine, it is expected to mount only IgM response in absence of *class switching* to IgG typically associated with protein antigens, PPSV is unique as it induces IgM, IgA and IgG antibodies; the IgG antibodies predominantly belong to the IgG2 subclass. However, just like other polysaccharide vaccines, repeated doses are not associated with a booster response. On the contrary, there is evidence to suggest hyporesponsiveness with repeated doses. Thus, not more than two life time doses are recommended for this vaccine.

#### Efficacy and Effectiveness

Most of the data on its efficacy and effectiveness is based on studies conducted in adults with hardly any study in children. Despite the fact that PPSV is much older than PCV, the evidence on efficacy and effectiveness of PPSV23 continues to be conflicting. Possible causes of conflicting results in various studies are poor methodological quality of clinical trials, low rates of laboratory confirmed invasive pneumococcal disease (IPD) and the nonspecificity and varying definitions used for pneumococcal pneumonia. Moreover, the likelihood and biologic plausibility that efficacy and effectiveness vary with age and presence and severity of underlying high-risk condition that increases the risk of contracting pneumococcal pneumonia further complicates the issue of measuring the efficacy and effectiveness of this vaccine. A systematic review

commissioned by WHO concluded that the evidence was consistent with a protective effect against IPD and pneumonia in healthy adults and against IPD in the elderly. However, there was no evidence of efficacy against invasive disease or pneumonia in other high risk populations with underlying disease. In fact, one Ugandan study in HIV-infected adults showed an unexpected *increased* risk of pneumonia among those vaccinated with PPSV23.

#### Safety

PPSV23 is a safe vaccine, both in terms of immediate serious adverse events and potential long-term adverse consequences. Local adverse effects like pain and redness is reported in 30–50% of vaccines, occurring more commonly in those administered the vaccine subcutaneously as compared to intramuscularly and more in second dose as compared to first dose of the vaccine.

#### Recommendations for Use

PPSV23 is not effective in children below 2 years of age and thus is not recommended in this age group. It is also not recommended for routine use for healthy children of any age. Indian Academy of Pediatrics (IAP) recommends that this vaccine should only be used in certain high-risk groups of children and that too in conjunction with PCV. *PPSV should never be used alone for prevention of PDs amongst high-risk individuals.* The first dose of the vaccine should be given at least 8 weeks after the last dose of PCV to children aged 2 years or older with certain underlying medical conditions (*vide infra*). The second dose of this vaccine should be given at the age of 5 years in these children. The dose is 0.5 mL to be given intramuscularly in deltoid muscle or subcutaneously.

When elective splenectomy, immunocompromising therapy, or cochlear implant placement is being planned; PPSV23 vaccination (along with PCV) should be completed at least 2 weeks before surgery or initiation of therapy. Following are the medical conditions for which PPSV23 (along with PCV) is indicated in the age group 24 through 71 months:

- *Immunocompetent children with chronic disease* like chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure); chronic lung disease (including asthma if treated with high-dose oral corticosteroid therapy); diabetes mellitus; cerebrospinal fluid leaks; or cochlear implant.
- *Children with anatomic or functional asplenia* (including sickle cell disease and other hemoglobinopathies, congenital or acquired asplenia, or splenic dysfunction).
- *Children with immunocompromising conditions* HIV infection, chronic renal failure and nephrotic syndrome, diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemia, lymphomas and Hodgkin disease; or solid organ transplantation, congenital immunodeficiency.

### PNEUMOCOCCAL CONJUGATE VACCINES

In this type of pneumococcal vaccines, the *Streptococcus pneumoniae* capsular polysaccharides are chemically coupled with an immunogenic carrier. These were developed to overcome the immunological limitations of PPSV. PCVs have good immunogenicity even in infants, induce immunological memory and offer long-lasting protection.

#### Older PCVs

The first PCV was 7-valent vaccine (PCV7) containing capsular polysaccharides of 7 serotypes (4, 6B, 9V, 14, 18C, 19F and 23F) conjugated individually to a nontoxic diphtheria cross-reactive material carrier protein (CRM197). It was first licensed in February, 2000 in USA. It was subsequently replaced by 13-valent PCV (PCV13) in February 2010. A second 7-valent vaccine with the outer

membrane protein (OMP) complex of *Neisseria meningitidis* as the protein carrier was also developed but not licensed. Similarly, one 9-valent and two 11-valent PCVs were also developed but never licensed.

### Currently Available PCVs

The two PCVs that have been licensed and currently available are 10-valent (PCV10) and 13-valent (PCV13). PCV10 covers three additional serotypes besides those in PCV7: 1, 5, and 7F. It contains 3 µg each of the capsular polysaccharides of serotypes 18C and 19F conjugated to tetanus and diphtheria toxoid respectively, 3 µg of serotype 4 and 1 µg of rest of the serotypes each individually conjugated to an OMP of nontypeable *Haemophilus influenzae* (NTHi) (Protein D). It contains aluminum phosphate as an adjuvant, but no preservative. It is marketed as a pre-filled syringe in India. Latex is contained in syringe component.

PCV13 covers serotypes 3, 6A and 19A in addition to those contained in PCV10. It contains 4 µg of the capsular polysaccharide of serotype 6B and 2 µg of rest of the serotypes each individually conjugated to a nontoxic variant of diphtheria toxin, CRM197 (CRM, cross reactive material). The vaccine also contains aluminum phosphate as an adjuvant but no preservative. It is also available in India as prefilled syringes that do not contain latex.

### PCVs in Pipeline

An Indian company with active support of Department of Biotechnology (DBT), Government of India is developing 15-valent vaccine containing two additional serotypes, 2 and 12F to existing PCV13. Merck is also developing 15-valent vaccine with two additional serotypes, 22F and 33F to existing PCV13. Both these formulations are using CRM197 as a carrier protein. **Figure 1** shows serotype composition of the PCV formulations that have been evaluated in phase III clinical efficacy trials or under clinical development.

### Immunogenicity

PCVs induce serotype-specific antibody response. There is evidence in favor of cross-protection for the serotypes within the same serogroup (e.g., 6A and 6B serotypes of the serogroup 6), but the same is not seen in some other serogroups (e.g., between 19A and 19F). However, there is absolutely no protection against the serogroups not included in the particular formulation. Both the currently available vaccines have good immunogenicity in

the dosage schedules indicated by the respective manufacturers. Both of these meet the serological correlates of protection, clearly defined by the WHO. These criteria include:

- IgG (for all common serotypes collectively and not individually) of equal to or more than 0.35 mcg/mL measured by the WHO reference assay (or an equivalent alternative).
- The serotype-specific IgG geometric concentration ratios.

### Efficacy

The efficacy of PCV has been evaluated in different populations in both developed and developing countries in different regions of the world and against a number of different clinical outcomes.

**Invasive pneumococcal disease** The vaccine has been shown to be very efficacious in preventing IPD due to the serotypes contained in the vaccine. In a systematic review and meta-analysis from seven studies, a pooled vaccine efficacy of 80% [95% confidence interval (CI) 58% to 90%,  $P < 0.0001$ ] was observed against vaccine type invasive disease and 58% (95% CI 29% to 75%,  $P = 0.001$ ) against total invasive disease (irrespective of serotype).

**Pneumonia** Testing the vaccine efficacy against pneumococcal pneumonia is challenging, since its microbiological diagnosis is extremely difficult (unless it is associated with bacteremia). Thus, most of the studies have been conducted to test efficacy of these vaccines against radiologically defined pneumonia, using a standardized WHO definition and process for interpreting radiographs. The pooled estimate of vaccine efficacy against radiologically defined pneumonia has been found to be 27% (95% CI 15% to 36%,  $P < 0.0001$ ). Further, studies in South Africa have also shown reductions in hospitalization with virus-associated lower respiratory infection, suggesting that co-infection with pneumococcus contributes to severity of disease, resulting in hospitalization; receipt of PCV reduces the risk of severe disease associated with respiratory viruses that requires hospitalization. Thus, the full impact of PCV on pneumonia extends beyond the impact on radiologically defined pneumonia.

**Otitis media** Efficacy data for acute otitis media (AOM) is available for two formulations of PCV7, PCV9 and PCV11. Efficacy of around 56% has been found for AOM due to the serotypes contained in the respective vaccine formulations. However, with PCV7 and PCV9, increases in AOM due to other serotypes of pneumococcus and other organisms increased, such that the overall impact on otitis media was not significant. Nevertheless, PCV7-CRM197

Formulation	Protein carrier	1	2	3	4	5	6A	6B	7F	9V	12F	14	18C	19A	19F	22F	23F	33F
PCV 7	CRM 197																	
PCV 7	OMP																	
PCV 9	CRM 197																	
PCV 10	Protein D, TT, DT																	
PCV 11	TT, DT																	
PCV 11	Protein D																	
PCV 13	CRM 197																	
PCV 15*	CRM 197																	
PCV 15**	CRM 197																	

**Figure 1** Serotype composition of the pneumococcal conjugate vaccine formulations that have been evaluated in phase III clinical efficacy trials or under clinical development

■ Serotypes in the vaccine □ Serotypes with cross protection \*Under production in India by the support of DBT \*\*Under production in US by Merck

was observed to protect against recurrent or more severe forms of AOM, including otitis requiring tympanostomy tube placement. With PCV11, the protection against vaccine-type pneumococcal otitis was not completely offset by increases in otitis by other serotypes of pneumococcus or other bacteria; vaccine efficacy against all otitis media of 33.6% (95% CL 21, 44%) was observed. In this trial, significant protection was also observed against AOM caused by NTHi with observed efficacy of 35% (95% CL 1.8, 57.4%); this protection was attributed to the immune response to Protein D of NTHi, which was the protein carrier in this formulation of the vaccine. This PCV11 was later re-formulated as PCV10 (serotype 3 was removed) and is now marketed as PCV10 only.

**Nasopharyngeal carriage** Efficacy studies have also been conducted with PCV7 for reduction in nasopharyngeal carriage of pneumococci. These studies have shown about 50% reduction in nasopharyngeal carriage of vaccine serotypes with 50% increase in nasopharyngeal carriage of non-vaccine serotypes, resulting in net zero effect on overall nasopharyngeal carriage of pneumococci.

### Vaccine Effectiveness

The countries which have included PCVs in their national immunization programs have shown reduction in vaccine type invasive disease, not only in the targeted children, but also in older populations as a result of the indirect effects of the vaccine through reduction in nasopharyngeal carriage and transmission of the organism. This has been shown not only in developed countries like the USA and UK, but also in developing countries like Kenya and Nicaragua in the recent years. Moreover, since the incidence and mortality from IPD is generally higher in developing countries, the overall reduction in morbidity and mortality is likely to be greater. The reduction in socioeconomic inequalities in morbidity from PD observed in the United States supports this assumption. However, at least one study in Australia failed to document any reduction in radiologically defined pneumonia. One trial using PCV9, conducted in a high mortality setting in Gambia, showed reduction in *overall mortality* by 16% (95% CL 3, 28). The evidence in favor of using PCVs in otherwise healthy children over 5 years of age and use in pregnant women to protect their newborns is currently not sufficient, although WHO continues to consider and monitor the upcoming data on these fronts.

The prevalence of serotypes in the community where the vaccine is being used obviously affects vaccine effectiveness significantly, since *Streptococcus pneumoniae* has over 90 serotypes and the serotypes that cause significant disease vary by age, disease syndrome, disease severity, geographic region, and over time. Further, each serotype has a distinct *personality*. While a wide variety of serotypes cause noninvasive diseases such as otitis media and sinusitis, serotypes 1, 5, 6A, 6B, 14, 19F, and 23F are common causes of IPD globally in children less than 5 years of age. Serotypes 1, 5, and 14 together account for 28–43% of IPD globally and for about 30% of IPD in 20 of the world's poorest countries; serotypes 23F and 19F are responsible for 9–18% of cases globally. Serotype 18C is common in regions with a large proportion of high-income countries (i.e., Europe, North America, and Oceania). Some serotypes such as 6B, 9V, 14, 19A, 19F, and 23F are more likely than others to be associated with drug resistance.

In the last two decades, another factor that has changed the serotype distribution is the introduction of PCVs themselves. Prior to introduction of PCVs, 6–11 serotypes accounted for more than or equal to 70% of all IPD occurring in children worldwide. The distribution has changed after introduction of PCVs. The countries which introduced PCV in national immunization schedule (i.e., routine vaccination) have demonstrated dramatic reduction in, and in some places virtual disappearance of IPD due to vaccine

serotypes. This has led to the serotypes not contained in the vaccine gaining importance. For example, introduction of PCV7 in the USA led to great reduction in the vaccine serotypes, especially serotypes 4, 6B and 9V, but has led to significant increase in other serotypes, especially 7F and 19A. Currently, 19A accounts for maximum cases of IPD in the USA. However, the increase in IPD due to nonvaccine serotypes has not been as much as the reduction in IPD due to vaccine serotypes in most of the regions or countries. Hence, significant net reduction in cases of pneumonia or IPD has been observed. Such surveillance data from developing countries is sparse. Thus, WHO strongly recommends continued surveillance for replacement serotypes, especially in developing countries where the potential for replacement may be different from that in industrialized countries.

### Vaccine Effectiveness of Partial or Incomplete Vaccination

Clinical trials have demonstrated the vaccine effectiveness of one dose of PCV13 of about 48%, two doses 87% and 2+1 doses 100%. One dose catch up for toddlers showed 83% effectiveness.

### Duration of Protection

Both the immunogenicity and the post marketing surveillance data has shown protective efficacy of the PCV vaccines lasting for over 6 years.

### Safety

Various formulations of PCVs have been shown to have an excellent safety profile. The most common (~ 10% of vaccines) adverse events observed are injection-site reactions, fever, irritability, decreased appetite, and increased and/or decreased sleep. Fever with temperature more than 39°C occurs in 1/100 to less than 1/10 vaccines, vomiting and diarrhea in 1/1,000 to less than 1/100, and hypersensitivity reactions and nervous system disorders (including convulsions and hypotonic-hyporesponsive episodes) are rare (in 1/10,000 to less than 1/1,000 of the vaccines).

## Recommendations for Healthy Children

### Indication

In India, both PCV10 and PCV13 are licensed for active immunization for the prevention of PDs caused by the respective vaccine serotypes in children from 6 weeks to 5 years of age. US (FDA) licensed PCV13 for use in the age group of 6–17 years also. Licensing for the latter age-group is under process in India (personal communication).

### Administration Schedule

For both PCV10 and PCV13, IAP recommends three primary doses at 6, 10, and 14 weeks, followed by a booster at 12–15 months of the age (3p+1 schedule). The booster can be given as early as 6 months after the third dose. In most developed countries, the primary doses are recommended at 2, 4 and 6 months rather than 6, 10 and 14 weeks of age. Further, based on data from immunogenicity studies and on effectiveness data in children who received incomplete courses of PCV, several countries adopted shortened schedules for use in their national immunization programs so as to cut down the cost of mass vaccination. The most common of these schedules are three primary doses with no booster (3p+0) and two primary doses with one booster dose (2p+1). The major limitation of the 3p+0 schedule is the likelihood of less efficacy against serotype 1, which is very invasive serotype and is a common cause of IPD in second year of life, when the antibody levels may be less in that age with this schedule. The

**Table 1** Recommended schedule for use of PCV13/PCV10 among previously unvaccinated infants and children by age at time of first vaccination

Age at first dose	Primary series		Booster dose	
	PCV13	PCV10	PCV13	PCV10
6 weeks–6 months	3 doses	3 doses	1 dose at 12–15 months*	1 dose at 12–15 months*
7–11 months	2 doses	2 doses	1 dose during second year	1 dose during second year
12–23 months	2 doses#	2 doses#	NA	NA
24–59 months	1 dose	2 doses#	NA	NA

NA = not applicable \*At least 6 months after the third dose; # At least 8 weeks apart  
Abbreviation: PCV, pneumococcal conjugate vaccine.

major limitation of 2p+1 schedule is that the antibody levels in the interval between the two primary doses and the booster dose may be lower for some serotypes like 6B and 23F. The 3p+0 and 2p–1 schedules are to be considered only for mass vaccination; they are not recommended for *individual protection* or office practice.

### Catch-up Vaccination

**Table 1** gives the schedule for catch-up vaccination.

### Route of Administration

The vaccines are given by injection into the anterolateral aspect of the thigh in infants and into the deltoid muscle in older age groups.

### Recommendations for High-risk Group of Children

Children less than 2 years of age in high-risk category (*vide supra*, section on PPSV) should receive all the doses of PCV10/PCV13 as recommended for healthy children. In addition, they should also receive PPSV23 after the age of 2 years, and at least 8 weeks after the last dose of PCV.

Children who have received PPSV23 previously also should receive recommended PCV13/PCV10 doses. For children aged 24 through 71 months with certain underlying medical conditions, administer one dose of PCV13/10 if three doses of PCV were received previously or administer two doses of PCV13/10 at least 8 weeks apart if fewer than three doses of PCV were received previously. A single dose of PCV13/10 is sufficient for previously unvaccinated children in the 6–18 years age group in the high-risk category.

As per the latest (November 2013) guidelines of IAP, preterm babies and very low birthweight (VLBW) infants are also considered in high-risk category for pneumococcal vaccination. These infants have up to 9-fold higher incidence of IPD in VLBW babies as compared to full size babies. PCV13/10 is strongly recommended in these babies on a priority basis.

### IN A NUTSHELL

- Two types of vaccines are currently available and licensed against pneumococcus (*Streptococcus pneumoniae*): Pneumococcal polysaccharide vaccine (PPSV) and pneumococcal conjugate vaccines (PCVs).
- PPSV being a polysaccharide vaccine, it is T-cell independent vaccine, poorly immunogenic below the age of 2 years, has low immune memory, lacks *booster effect* with repeated doses, and does not provide herd immunity.
- PPSV is mainly indicated for certain high-risk individuals along with PCVs. It should never be used alone for prevention of pneumococcal diseases amongst high-risk individuals.
- A wide variety of serotypes cause noninvasive diseases such as otitis media and sinusitis, serotypes 1, 5, 6A, 6B, 14, 19F, and 23F are common causes of IPD globally in children less than 5 years of age.
- Currently, two PCVs are licensed and available, PCV10 and PCV13. PCV10 includes three additional serotypes besides those in PCV7: 1, 5, and 7F. PCV13 includes serotypes 3, 6A and 19A in addition to those contained in PCV10.
- Both PCVs have been shown to be very efficacious in preventing IPD due to the serotypes contained in the vaccine, however, they have modest impact on overall pneumonia.
- The countries which have included PCVs in their national immunization programs have shown reduction in vaccine type invasive disease, not only in the targeted children, but also in older populations as a result of the indirect effects of the vaccines.
- Emergence of *replacement disease* caused by nonvaccine serotypes owing to vaccine pressure and other trends has caused serious concerns.
- The increase in IPD due to *nonvaccine serotypes* has not been as much as the reduction in IPD due to vaccine serotypes in most of the regions or countries.
- WHO strongly recommends continued surveillance for replacement serotypes, especially in developing countries where the potential for replacement may be different from that in industrialized countries.

## Chapter 23.17

# Rotavirus Vaccines

Gagandeep Kang

Rotaviruses, discovered in humans in 1973, are now known to be the primary etiological agents of severe gastroenteritis in children less than 5 years of age, estimated to be the cause of nearly 40% of hospitalizations for acute gastroenteritis. Nearly 500,000 children die every year from rotavirus, mainly in developing countries, and this figure represents about 5% of all deaths in children younger than 5 years. Mortality is greatest in South Asia and sub-Saharan Africa—approximately 100,000 or more children die of rotavirus disease in India alone.

### VIRAL STRUCTURE AND DIVERSITY

Rotaviruses are triple layered particles, with the middle coat protein VP6 determining the group, and the outer coat proteins VP7 (G-) and VP4 (P-) responsible for the further classification into genotypes or serotypes. Human rotaviruses are mainly group A and VP7 genotypes G14, G9 and G12 and VP4 P genotypes P[4], P[6] and P[8] are the common strains seen worldwide. G9 strains emerged during the 1990s, and in the past decade, G12 strains have been identified in many parts of the world. Data from a surveillance network run by the Indian Council for Medical Research from 2005 to 2008, showed that the proportion of gastroenteritis hospitalizations associated with rotavirus was 39% and that the most common strains were G2P [4] (25.7%), G1P [8] (22.1%), and G9P [8] (8.5%). G12 strains were seen in combination with P[4], P[6] and P[8] and together made up 6.5% of strains.

### CLINICAL DISEASE AND EPIDEMIOLOGY

Virtually all children worldwide have been infected by the time they reach 2–3 years of age. Most symptomatic episodes occur between 3 months and 2 years of age with a peak incidence between 7 months and 15 months. Rotavirus infection is transmitted mainly by the fecal-oral route and contact and has a short incubation period of between 1 day and 3 days. Rotavirus disease is characterized by the sudden onset of acute watery diarrhea, often accompanied by fever and vomiting. Treatment of rotavirus illness is limited to supportive measures, such as oral or intravenous rehydration, and the only specific method to combat rotavirus disease is vaccination. In the absence of vaccines, the incidence of rotavirus disease was similar in both industrialized and developing countries, suggesting that although improvements in hygiene did delay the age of infection, viral gastroenteritis continued to occur in settings with good water supply, hygiene, and sanitation.

### ROTAVIRUS VACCINES

#### Early Vaccines

All currently licensed rotavirus vaccines are live, orally administered vaccines that aim to mimic the protection given by naturally occurring rotavirus infection. Research to develop a safe, effective rotavirus vaccine began in the mid-1970s. The early studies with monovalent animal rotavirus based vaccines gave inconsistent results, so further vaccine development efforts began to use either naturally attenuated human rotavirus strains or reassortant rotavirus strains bearing a human rotavirus gene for the VP7 protein together with the other genes from an animal rotavirus strain. The first multivalent live oral reassortant vaccine developed, RRV-TV (RotaShield made by Wyeth Ltd.), contained a mixture

of four virus strains, and was evaluated in field trials and proved highly effective (80–100%) in preventing severe diarrhea due to rotavirus. After this vaccine was included in the immunization schedule in USA and over 600,000 infants immunized, cases of vaccine-associated intussusception were reported. The period of greatest risk of intussusception was shown to be 3–10 days after the first of three oral doses.

#### Currently Licensed Vaccines

In 2014, there were four licensed vaccines of the world, of which two have been used by multiple countries in public immunization programs. One pentavalent human-bovine (WC3) reassortant (G1, G2, G3, G4 and P[8]) live-attenuated, oral vaccine, RotaTaq, was developed as a three dose series by Merck Research Laboratories. A live-attenuated human rotavirus G1P[8] vaccine (strain 89-12) was originally developed by tissue culture passage of a rotavirus isolate from an infant, and developed as Rotarix, given as a two dose series at 1–2 month intervals, by GlaxoSmithKline Biologicals. Both were tested in 60,000–70,000 children in northern and Latin America and northern Europe and showed excellent efficacy against severe rotavirus gastroenteritis and no evidence of an intussusception risk.

These two rotavirus vaccines were licensed and introduced into national programs in some parts of the world in 2006, and data have emerged on the impact of vaccination on morbidity and mortality. A study from Mexico published in 2010 suggests that the introduction of rotavirus vaccine resulted in substantial reduction in rotavirus deaths. Nationally representative data on morbidity in several high income countries showed a reduction of 28–50% in hospitalization rates for acute gastroenteritis for children under-5 years of age. Both the vaccine showed efficacy against viruses of all serotypes. Because the changes in rotavirus activity appeared more pronounced than might be attributed to direct protective effects of vaccination alone, the surveillance suggests that vaccination of a proportion of the population might offer indirect benefits to unvaccinated children (i.e., herd immunity) by reducing transmission of rotavirus in the community.

Postmarketing surveillance in several countries also identified a low-risk of intussusception with either vaccine (approximately 1–5 cases per 100,000 infants and is mainly in the first week after the first or second dose of vaccine). The vaccines were also evaluated in developing countries, and showed much lower efficacy (**Table 1**) than the approximately 90% efficacy that had been reported in industrialized countries. Effectiveness studies in Bolivia and Nicaragua reported approximately 50–70% effectiveness in prevention of hospitalized rotavirus gastroenteritis, while effectiveness was less than 40% in Bangladesh. Both vaccines demonstrated reduced vaccine efficacy or effectiveness, but had a high public health impact because of the high burden of disease in these regions. Little is known about the reasons why oral vaccines are less efficacious in developing countries, but several factors such as nutritional status, maternal antibodies, competing enteric infections, altered composition of intestinal microbiota and age at infections have been proposed.

Given the low risk of intussusception and the major impact that the vaccines have had on disease, resulting in decreased diarrheal hospitalizations and mortality wherever the vaccines have been used for several years, the World Health Organization (WHO) has recommended that rotavirus vaccine be used in the national immunization programs of all countries.

In India, 116E, a human neonatal, naturally reassorted G9P[11] strain of Indian origin has been evaluated in phase I–III studies, and shown to have 56% protection in the first year of life (**Table 1**) and 49% in the second year. It was also effective against gastroenteritis caused by multiple serotypes. This vaccine, called

Rotavac, is anticipated to be priced at 1US\$ a dose and hence may be affordable for resourced-limited countries.

In Vietnam, Rotavin-M1, a human attenuated G1P[8] strain, has been developed for local use and was licensed based on immunogenicity studies in adults and children. Efficacy results are awaited.

**Table 1** Efficacy of rotavirus vaccines in the Asian and sub-Saharan Africa region

	Vaccine	No. of children enrolled	Percent efficacy (CI)
<i>Asia</i>			
Bangladesh	RotaTeq	1136	42.7 (10.4–63.9)
Vietnam		900	63.9 (7.6–90.9)
Taiwan	Rotarix	1141	96.1 (85.1–99.5)
Singapore		6542	85.1–99.5
Hong Kong		3025	96.1 (85.1–99.5)
India	Rotavac	3799	53.6 (35.0–66.9)
<i>Africa</i>			
South Africa	Rotarix	1944	76.9 (56.0–88.4)
Malawi		1030	49.4 (19.2–68.3)
Ghana	RotaTeq	2162	55.5 (28.0–73.1)

Mali		1842	17.6 (–22.9–45.0)

### Vaccines in Development

Other vaccines are in development in India, Australia, Indonesia, Brazil and China. These candidates belong to two categories: human neonatal strains, and human-bovine reassortant strains. A neonatal strain vaccine candidate based on RV3 is in development in a partnership between Australia and Indonesia. Other manufacturers in India, Brazil and China are developing vaccines based on the UK bovine strain, which has been licensed from the National Institutes of Health, and is a bovine-human reassortant. These candidates are currently in phase II or III trials.

In order to improve the performance of rotavirus vaccine, non-replicating vaccines are being developed for parenteral use and have just entered early phase trials. Although we do not completely understand the mechanism of protection in rotavirus immunization, it is possible that a systemic response may be sufficient to protect the individual child. It is not known whether viral replication in humans is an absolute prerequisite for mounting a protective immune response, but it is likely that delivery of nonreplicating antigens parenterally could induce a stronger and sustained immune response.

### RECOMMENDATIONS FOR VACCINATION

For children, Rotarix is given as a two doses schedule 1–2 months intervals beginning at 6–12 weeks of age along with routine childhood vaccines, while RotaTeq is administered as three doses at 1–2 months intervals beginning at 6–12 weeks of age. One study evaluating the immunogenicity of Rotarix vaccine at multiple sites in India found 27% of the 8-week-old infants initially seropositive. The 1 month post-dose two seroconversion rates observed in the vaccinated group was 58.3%. For RotaTeq, 20% of 6–12 week old

Indian infants were initially seropositive. Overall, 83% infants demonstrated seroconversion, the percentage with 3-fold increase in neutralizing antibody titer was 38.2%, 14.7%, 30.4%, 37.2% and 30.4% for G1, G2, G3, G4 and P8 respectively.

Fever, diarrhea and vomiting are the most common adverse events with both vaccines and occur in less than or equal to 10% of children and are generally self-limiting. Contraindications for vaccination include hypersensitivity to vaccine or to any ingredient, severe combined immunodeficiency disease, infants with uncorrected congenital gastrointestinal malformation (such as Meckel diverticulum) that would predispose for intussusception or a history of intussusception.

Although, recommendations and package inserts state that the vaccines should not be given after 32 weeks of age, the WHO has stated that for countries introducing rotavirus vaccination, the benefit of preventing rotavirus gastroenteritis morbidity and mortality should be considered when decided whether or not to broaden the age window for administration.

It has been estimated that with 70% coverage in the 72 countries eligible for funding by the GAVI alliance, vaccinating one single birth cohort would prevent about 55% of rotavirus associated deaths. Using the WHO's cost-effectiveness threshold of per-capita GDP, the vaccines would be cost-effective in 94% of GAVI eligible countries at a cost of 25 international dollars for each immunized child. However, in countries with large birth cohorts as in India, there are many factors which determine the ability of a national health-care system to deploy a new vaccine.

#### IN A NUTSHELL

1. Rotavirus is the leading cause of severe childhood gastroenteritis in both in developed and developing countries.
2. Two rotavirus vaccines Rotarix (GSK Biologicals) and RotaTeq (Merck Research Laboratories), are licensed in many countries in the world.
3. Rotavac is an Indian vaccine developed from 116E isolated at AIIMS, and has 53.6% efficacy against severe rotavirus vaccines caused by any serotype.
4. Rotavirus vaccine efficacy is lower in developing nations but still has a substantial public health impact.
5. Intussusception is a rare adverse event which appears to occur after the first or second dose of vaccine at a rate of 1 in 20,000 to 1 in 100,000 vaccines.
6. The World Health Organization has recommended that all national immunization programs should adopt these vaccines.

## Chapter 23.18

# Cholera Vaccines

Monjori Mitra

The annual global burden of cholera is estimated to be 3–5 million cases with 100,000–130,000 deaths (WHO estimates). Of the 32 countries that reported deaths from cholera, 20 were on the African continent which accounted for nearly 45% of the global total. In May 2011, the World Health Assembly recognized the re-emergence of cholera as a significant global public health problem and adopted resolution WHA 64.15, calling for implementation of an integrated and comprehensive global approach to cholera control.

**Disease burden in India** Cholera is endemic in India where only 25% of the population has access to piped water supply and sanitation. More than 95% strains are serotyped as Ogawa. Cholera is reported to be more common in children above 5 years of age. A recent study from Kolkata showed the highest incidence in children below the age of 2 years, highlighting a need for protection in early age.

### VACCINES

Vaccination against cholera was first tested in the 19th century and played a role in controlling epidemics. Injectable (parenteral) whole cell vaccines were used in the 1960s and 1970s, but were withdrawn as their efficacy was thought to be low and short-lived, and had high rate of adverse effects. Subsequently two types of oral cholera vaccines were developed. Oral vaccine is always preferable as it has been seen that the efficacy of injectable vaccine is around 50% only and moreover, it does not prevent introduction of cholera into a country or interrupt transmission (no herd immunity). Also it cannot prevent development of carrier state. For all these reasons, parenteral vaccine is not recommended by WHO for controlling epidemics.

### Oral Cholera Vaccines

#### *Killed Whole Cell Oral Cholera Vaccine*

Inactivated whole cell bivalent cholera vaccines against *Vibrio cholerae* O1 and O139 were developed for public health purposes in Vietnam in the 1990s. This bivalent vaccine has been found to be safe and to confer significant protection against El Tor cholera in both children and adults and has over the last decade being used in Vietnam to protect against cholera.

**Dukoral-TM (Crucell, Netherlands)** This vaccine contains a mixture of killed *V. cholerae* O1 bacteria and the non-toxic B subunit of cholera toxin (CTB). It showed 85% protection for the first 4–6 months and 60% protection for 2 years after a primary regimen of two or three doses. The protection declined substantially in the third year and was evident against *V. cholerae* O1 El Tor only in the first year for individuals younger than 5 years. Because heat labile toxin of enterotoxigenic *Escherichia coli* (ETEC) cross reacts with CT, this vaccine also provides short-term protection against ETEC. The limitation of the vaccine is that the vaccine is supplied with a buffer (as CTB is sensitive to stomach acid), which is to be dissolved in a glass of water. This needs safe drinking water and it also needs to be stored at 2–8°C. Further, as this vaccine does not have O139 strain, it is not recommended in India.

**Shanchol-TM (Shantha Biotechnics, India)** This vaccine developed and licensed in India in 2009 contains the same *V. cholerae* O1 whole-cell strains as Dukoral, at different doses, and killed *V. cholerae* O139 bacteria but not the B subunit component. It contains both Ogawa and Inaba serotypes of classical and El Tor biotypes with a recombinant B subunit of oral cholera toxin. A

large Phase III study in Kolkata (12,000 + participants age 1 year and above) showed over 60% protection against cholera. The vibriocidal antibody response rate was 80% in children and 53% in adults. Shanchol-TM is recommended for children 1–5 years. Two doses are given 14 days apart. Cumulative protective efficacy of the vaccine at 5 years was 65% and point estimates by year of follow-up suggested no evidence of decline in protective efficacy.

#### *Live Attenuated (CVD 103-HgR) Oral Cholera Vaccine*

CVD 103-HgR (Orochol-TM or Mutachol-TM) is a single dose live attenuated vaccine consisting of genetically manipulated classical *V. cholerae* O1 strain—available since 1994. Safety profile is good due to poor colonization in the human intestine. As the vaccine strain is live, maintenance of cold chain is needed to preserve the bacteria. The bacteria must also be protected from stomach acid, which is achieved by formulating and packaging of the vaccine with a buffer. The vaccine efficacy is near 60% for 6 months but does not any protection against O139 strain; long-term protection is also doubtful. This vaccine may be useful in prevention of cholera before or during epidemic.

#### *Herd Immunity Conferred by Killed Oral Cholera Vaccines*

Killed oral cholera vaccines confer significant herd protection to neighboring non-vaccinated individuals. This effect was attributed to vaccine induced reduction of fecal excretion of vibrios in vaccinated individuals giving rise to less environmental contamination and thus reducing fecal-oral transmission. Use of these vaccines could have a major effect on the burden of cholera in endemic settings.

### Cholera Vaccine in Epidemic Situation

In a case of cholera outbreak, a reactive vaccination campaign with a two-dose vaccine is almost impossible. Ideally a single dose-vaccine requiring no buffer and no cold chain, easy to administer, and providing long-term protection should be preferred. Dukoral-TM thus is not suitable for mass vaccination in epidemic situation. However, Shanchol-TM was recently found effective in response to a cholera outbreak in Guinea. In view of limited evidence, vaccination with the current internationally available prequalified vaccine is not recommended once a cholera outbreak has started.

### Future Vaccines

A number of other live oral vaccines are under development in the USA (Peru 15, CVD 110, 111, 112) and in Cuba (Cuban 638 strain). Results are promising and phase II and III trials are planned. Safety and immunogenicity study has also been conducted among Bangladeshi adults. Live oral vaccine against O139 is also undergoing safety and efficacy trials. A research on polysaccharide conjugate vaccine for cholera is currently being conducted in France and USA for parenteral use and evaluations are planned in countries with endemic cholera.

### IN A NUTSHELL

1. Parenteral whole cell vaccines, used initially during 1960s and 1970s, are no longer available. They were withdrawn due to poor efficacy and high reactogenicity.
2. Two types of oral cholera vaccines, killed and live attenuated are now currently in use globally.
3. A killed whole-cell oral cholera vaccine (Shanchol-TM) is currently available in India with reasonably good efficacy and long-term protection.
4. Shanchol-TM is recommended for children above 1 year of age in a schedule of two doses given 14 days apart.

## Chapter 23.19

# Varicella Vaccine

Rakesh Kumar

Available vaccine against varicella is quiet effective if vaccination is done as per the recommendations. However, varicella vaccination has not yet found a place in our National Immunization Schedule for its high cost and varicella not being a high priority health problem for India.

### LIVE VARICELLA VACCINE

In India only single antigen (monovalent) vaccine is available at present. Vaccine is made up of live-attenuated Oka strain of Varicella-zoster virus (VZV). An FDA approved quadrivalent vaccine (MMR-V), containing antigens for MMR and varicella, is available in USA. A higher concentration Oka strain vaccine is licensed by the FDA since 2006 which reduces the risk of herpes zoster and postherpetic neuralgia in people 60 years and older. However, it is not yet available in India. Monovalent varicella virus vaccine is lyophilized and should be stored at conditions prescribed by manufacturers. Reconstituted vaccine should contain a minimum of 1,000 plaque-forming units (PFU) in each 0.5 mL dose. Each 0.5 mL dose also contains 12.5 mg of gelatin, trace amounts of neomycin and fetal bovine serum along with sucrose.

### Vaccination Schedule, Dosage, Site and Route

Recommended schedule for primary active vaccination for children is first dose at 15–18 months and second dose anywhere between 4 years and 6 years. Second dose can be given earlier with at least a gap of 3 months in children less than 12 years. For older children and adults second doses given at an interval of 4–8 weeks completes active immunization. For postexposure prophylaxis vaccine dose is to be given within 3–5 days postexposure and second dose should be given as above.

### Vaccine Efficacy

Single dose vaccination (previously recommended) had lower efficacy of around 70–85% compared to more than 98% efficacy of second dose schedule as assessed over at least 10 years post-vaccination. Efficacy for preventing severe form of varicella is almost 100%. Also chances of breakthrough varicella after second dose schedule are almost 1/3rd as compared to single dose. The concentration of varicella antibody [ $> 5$  gp enzyme-linked immunosorbent assays (ELISA) units/mL] tested 6 weeks after immunization is known to confer vaccine efficacy rate of 95.5%.

### Adverse Reactions

Local reactions include pain, soreness, swelling and erythema, pruritus, hematoma, induration, stiffness, fever and rash. Around 5% of vaccines can develop vaccine virus related mild varicella like rash 2–3 weeks after vaccination. Anaphylaxis and Stevens-Johnson syndrome can be rare potentially serious complications. Ataxia, encephalitis, stroke, idiopathic thrombocytopenic purpura, and pneumonia, although reported after varicella vaccination, are very rare.

### Breakthrough Disease

Breakthrough varicella is defined as wild-type VZV infection occurring more than 42 days after vaccination. In cases of breakthrough disease, the median number of skin lesions is

commonly less than 50 (as against  $> 200$  in varicella in unimmunized cases). In addition, vaccine recipients have fewer vesicular lesions (have atypical lesions with papules not progressing to vesicles), shorter duration of illness, and lower incidence of fever. Secondary attack rate for breakthrough varicella is only 15% compared to 95% for varicella in unimmunized persons. Varicella occurring within 2 weeks after vaccination is due to wild VZV infection acquired before vaccine had its effect. Varicella occurring between 2 weeks and 42 days of vaccination can be either because of vaccine VZV or due to wild VZV and tends to be less severe compared to unimmunized persons.

### Catch-up Vaccination

If a person of any age has missed vaccination in early childhood, two doses of vaccine are administered at an interval of at least 4 weeks (3 months for  $< 12$  years) when there is no evidence of immunity against varicella. If only one dose is given previously and there is no evidence of immunity against varicella second dose is to be administered.

### Postexposure Prophylaxis

There are three options available for postexposure prophylaxis of varicella infection. First option being active vaccination as discussed above. Vaccination within 3 days of exposure to rash is more than or equal to 90% effective in preventing varicella whereas vaccination within 5 days of exposure to rash is approximately 70% effective in preventing varicella and 100% effective in modifying severe disease. Second option is of passive immunization with varicella-zoster immunoglobulin (VZIG). Third option of chemoprophylaxis with acyclovir also seems effective but there are no studies documenting its efficacy in preventing transmission after exposure. Indications for using VZIG as part of postexposure prophylaxis are: (1) Immunocompromised patients without evidence of immunity after direct exposure to varicella, including patients with primary and acquired immune-deficiency disorders, patients with neoplastic diseases, and those receiving immunosuppressive treatment. Patients receiving monthly high-dose intravenous immune globulin (IVIG) ( $\geq 400$  mg/kg) are likely to be protected and probably do not require VZIG if the last dose of IVIG was administered less than or equal to 3 weeks before exposure. (2) Healthy newborns where mother developed varicella between 5 days prior to delivery to 2 days after birth and premature newborns with exposure anytime during neonatal period. (3) Pregnant women without evidence of immunity against varicella. VZIG is supplied in 125-U vials. The recommended dose is 125 units/10 kg of body weight intramuscular, up to a maximum of 625 units (5 vials). The minimum dose is 125 U. Only preparation available in India is given at a dose of 0.2–1.0 mL/kg diluted in normal saline as intravenous infusion over 1 hour.

Any person receiving VZIG should subsequently receive varicella vaccine (if not contraindicated) but after an interval of 5 months. Administration of VZIG prolongs incubation period of varicella infection to up to 28 days (against usual average of 14 days), so patients receiving VZIG should be observed for appearance of signs or symptoms of varicella for at least 28 days.

### Contraindications

It is contraindicated in persons with history of severe anaphylactic reaction to vaccine or its components. It is also contraindicated in pregnancy. It should not be given to children who have congenital or acquired T-lymphocyte immunodeficiency, leukemia, lymphoma, malignant neoplasms affecting lymphoreticular system and children on long-term immunosuppressive therapy.

### Precautions

Varicella vaccine should not be administered to people who have moderate or severe illness, with or without associated fever. It should be administered with precaution in person who has recently received blood products or immune globulins or has a family history of immunodeficiency. A child who has thrombocytopenia or a history of thrombocytopenic purpura also needs close observation for deteriorating platelet counts.

### Vaccination of Immunocompromised Children

Children with humoral immune deficiencies can safely be immunized, but not those having T-cell defects. It can be given to HIV positive patients when CD4+ T-cell count is more than or equal to 15% of age related cut-off. Children on high dose systemic steroids (2 mg/kg/day of prednisone or its equivalent or 20 mg/day of prednisone or its equivalent) for more than 14 days should be vaccinated only after 1 month of discontinuation of high dose. Children on any other form of steroid therapy like inhaled, topical or nasal steroids can be safely administered varicella vaccine.

## INDIAN ACADEMY OF PEDIATRICS RECOMMENDATIONS

Indian Academy of Pediatrics (IAP) recommends that all healthy children should be offered varicella primary vaccination with first dose at 15–18 months and second dose anytime between 4 years and 6 years of age. High-risk populations (listed below) should also be actively vaccinated.

### High-risk Conditions Needing Varicella Vaccination

- Children with humoral immune deficiencies.
- Children with HIV infection but with CD4 counts 15% and above the age related cut-off.
- Leukemia but in remission and off chemotherapy for at least 3–6 months.
- Children on long-term salicylates. Salicylates should be avoided for at least 6 weeks after vaccination.
- Children likely to be on long-term steroid therapy. The vaccine may be given at any time if the children are on low dose steroids/alternate day steroids but only 4 weeks after stopping steroids if the patients have received high dose steroids (> 2 mg/kg) for 14 days or more.
- In household contacts of immunocompromised children.
- Adolescents who have not had varicella in past and are known to be varicella IgG negative, especially if they are leaving home for studies in a residential school or college.
- Children with chronic lung or heart disease.
- Seronegative adolescents and adults if they are inmates of or working in the institutional setup, e.g., school teachers, daycare center workers, military personnel and health-care professionals.

- For postexposure prophylaxis in susceptible healthy nonpregnant contacts.

### Criteria for Adequate Immunity Against Varicella

- Documentation of two appropriately timed doses of varicella vaccine.
- Laboratory evidence of immunity or laboratory confirmation of disease.
- Varicella diagnosed by a health-care professional or verification of history of varicella disease.
- History of herpes zoster diagnosed by a health-care professional.

### IN A NUTSHELL

1. An efficacious vaccine against varicella is available with almost 100% efficacy against moderate to severe disease after two doses.
2. Indian Academy of Pediatrics recommends that varicella vaccination should be offered to all children (> 1 year) with special consideration to high-risk groups.
3. Two doses are recommended for all ages with interval of at least 3 months for less than 12 years and 4–8 weeks for more than 12 years old.
4. Immunodeficiency, lymphoreticular malignancies, immunosuppressive drugs, previous severe reaction to vaccine and pregnancy are important contraindications.
5. Postexposure prophylaxis includes vaccination within 3–5 days with varicella-zoster immunoglobulin in some special situations with or without acyclovir.
6. The varicella vaccine is not yet included in the Universal Immunization Program (UIP) of India.

## Chapter 23.20

# Hepatitis A Vaccine

Vikram Gagneja, AJ Chitkara

Hepatitis A is a vaccine-preventable, acute, self-limiting disease of the liver caused by the hepatitis A virus (HAV) which is transmitted primarily via the fecal/oral route either through ingestion of contaminated food and water or through direct contact with an infectious person.

The incidence of hepatitis A is strongly correlated with socioeconomic indicators; with increasing incomes and access to clean water and adequate sanitation, the incidence of HAV infection decreases. India has been hyperendemic for HAV infection. Studies conducted in the 2000s observed that nearly 90% of adolescents, adults, and most children acquire immunity to HAV infection in their preschool years. However, recent studies have indicated a shift in epidemiology of HAV infection and shown significant decrease in seropositivity over the years. The overall seroprevalence of HAV in the group aged 6–10 years (50.3%) was significantly higher than in the group aged 18 months to 6 years (30.3%). The seroprevalence of HAV is higher in community with poor access to education and potable drinking water.

## ACTIVE IMMUNIZATION

The best way of giving cost effective and long-term protection is by active immunization which can be achieved by giving formaldehyde *inactivated vaccines* produced in several countries and which are the most commonly used globally or *live-attenuated vaccines*, which are manufactured in China and available in several other countries. Children younger than 12 months should receive passive prophylaxis as HAV is not licensed for this age group.

## Inactivated Hepatitis A Vaccines

**Composition** HAV is propagated in human fibroblasts. Following purification from cell lysates, the HAV preparation is formaldehyde-inactivated. Most available vaccines are adjuvanted by adsorption to aluminum hydroxide. One available vaccine uses a virosome adjuvant. Inactivated hepatitis A vaccines are currently available in single-dose presentations and most are formulated without preservative. For children, several manufacturers provide a half-volume presentation of the vaccine with the same antigen concentration as the adult formulation. Inactivated hepatitis A vaccines should be refrigerated at 2–8°C; the vaccines should not be frozen. When stored at the recommended temperature, the shelf-life for inactivated hepatitis A vaccines ranges between 24 months and 36 months, as specified by the manufacturers.

**Dosage and schedule** Combined vaccines that include hepatitis A and B or hepatitis A and typhoid have been developed, mainly intended for use in adult travelers. Inactivated hepatitis A vaccines are licensed for use in persons older than or equal to 12 months of age and complete vaccination schedule consists of two doses with an interval of 6–12 months; however, the interval between the doses is flexible and can be extended to 18–36 months. Few studies have shown this interval to be as big as 54 months. Hepatitis A vaccines can be administered simultaneously with vaccines like diphtheria, pertussis, tetanus (DPT), polio, *Haemophilus influenzae* type B (Hib), measles, mumps, rubella, typhoid, hepatitis B, cholera, Japanese encephalitis, rabies and yellow fever, without biologically significant interference in the immunogenicity, reactogenicity or safety of the individual vaccines.

**Immunogenicity and efficacy** All inactivated hepatitis A vaccines are highly immunogenic and gives 95% protective efficacy following second booster. Antibody levels ranging from 10 IU/mL to 33 IU/mL, using different assays, have been proposed as the threshold for protection from HAV infection in humans. Within 2–4 weeks of the first dose of inactivated hepatitis A vaccine, up to 100% of immunocompetent children and young adults achieve anti-HAV immunoglobulin G (IgG) titers over 20 mIU/mL and this protection persisting 9–11 years after two doses has been reported in the studies. Using a cut-off of greater than or equal to 20 mIU/mL, the median predicted duration of protection was estimated at 45 years.

**Safety** The overall safety profile of all formaldehyde-inactivated hepatitis A vaccines has been excellent, irrespective of schedule and manufacturer. Except for some local reactions (soreness or tenderness at injection site), headaches (rarely), no vaccine-related, serious adverse events has been reported. The only precaution and contradiction of hepatitis vaccine is hypersensitivity to any of the vaccine components. Inactivated hepatitis A vaccines are well tolerated in patients with mild-to-moderate chronic liver disease, in liver and renal transplantation recipients and in dialysis patients. The safety of these vaccines during pregnancy has not been confirmed, but because they are prepared from inactivated virus the risk to the developing fetus is likely to be negligible.

## Live-attenuated Hepatitis A Vaccine

**Composition** Two live-attenuated hepatitis A vaccines, based on the viral H2 strain and on the L-A-1-strain, have been licensed in China since 2008 for subcutaneous administration in children aged older than or equal to 1 year. These live vaccines are attenuated through multiple cell culture passages and subsequently propagated in human diploid embryonic lung fibroblast cells.

**Dosage and schedule** The live-attenuated vaccine is administered as a single subcutaneous dose. Experience during clinical trials and through passive surveillance did not identify any substantial safety concerns related to the Chinese live-attenuated hepatitis A vaccines. However, as with most other live-attenuated vaccines, these vaccines are not recommended for use in pregnant women and in immunocompromised patients.

**Safety and immunogenicity** In a multicenter study conducted in India, single dose schedule of live-attenuated hepatitis A vaccine was found to be immunogenic and tolerable with minimal reactogenicity. Safety profile was also satisfactory in the study population. The persistence of protective antibodies has been documented for 5 years after a single dose and the follow-up continues.

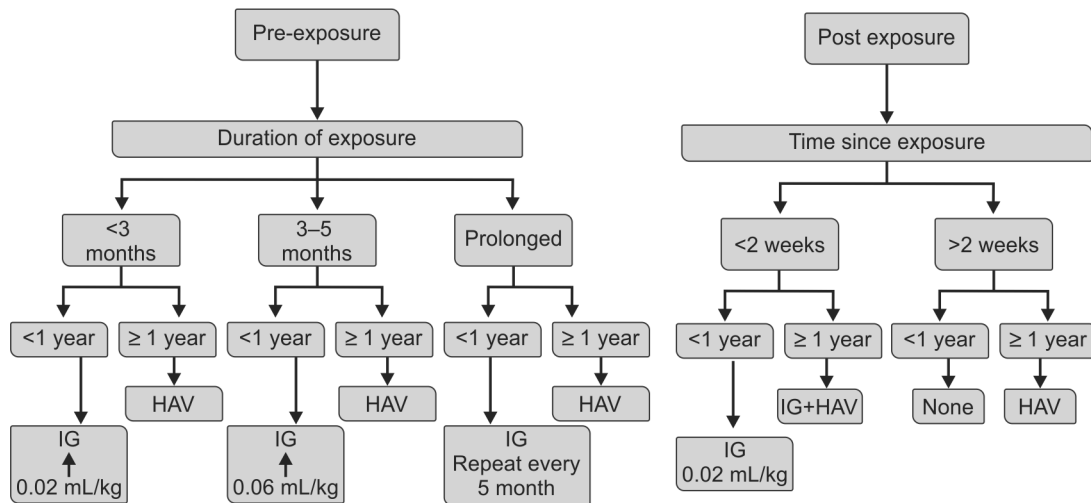

## Pre-exposure Prophylaxis

Pre-exposure prophylaxis for all children older than 12 months of age with either vaccine schedule and catch-up vaccination of unimmunized children from 2 years to 18 years of age in view of changing epidemiology should be considered. International travelers are at high-risk of getting hepatitis infection especially those travelling from low endemic area to high endemic area are candidates for routine prophylaxis with HAV. The Centers for Disease Control and Prevention (CDC) recommends combination of active and passive immunization for international travelers as per age and duration of likely exposure (**Flow chart 1**).

## Postexposure Prophylaxis

The use of hepatitis A vaccine rather than passive prophylaxis with Ig should be considered for travelers to areas of higher hepatitis.

**Flow chart 1** Recommendations for pre- and postexposure prophylaxis

Abbreviations: IG, immunoglobulin; HAV, hepatitis A vaccine.

An endemicity and postexposure prophylaxis for contacts of acute cases of hepatitis A in closed or institutional settings is cost-effective and as good as passive prophylaxis (**Flow chart 1**).

### Recommendations for Use

**Routine use** Hepatitis A vaccine is licensed for use in children above 12 months and older with two doses schedule when using inactivated vaccine and single dose with live-attenuated vaccine. The adult formulations are recommended for people 19 years of age and older. As per IAP recommendations the hepatitis A vaccine can be started any time after 12 months of age and second dose can be given between 6 months and 12 months after the first dose. The dose is 0.5 mL and 1 mL in pediatric and adult respectively by intramuscular route.

**Catch-up vaccination** It can be considered in children between 2 years and 18 years without the need for preimmunization serological testing. In cases where there has been missed or lapsed schedule the immunization should be completed at immediate contact with person. The vaccine is highly efficacious and this protective efficacy in preventing clinical HAV infection is 94–100%. Although the same vaccine is preferable for two dose schedule but vaccine interchangeability between different brands has no effect on immunogenicity.

### Recommendations in Special Circumstances

High-risk groups for hepatitis A infection include those who are at increased risk of HAV exposure as well as those at increased risk of a serious clinical outcome after acquiring the infection. These include those requiring life-long treatment with blood products, such as hemophiliacs, men who have sex with men, workers in contact with nonhuman primates and injection drug users. Vaccination of high-risk groups offers benefits to individual recipients but there is little evidence that such vaccination efforts are successful in reaching high coverage among targeted groups and effective in reducing reported rates of hepatitis A in the general population. Practical constraints, including staff turnover, may limit the effectiveness of vaccinating food handlers to prevent common-source food-borne hepatitis A. People with chronic liver diseases are at increased risk of fulminant hepatitis A, susceptible patients should receive routine immunization with hepatitis A vaccine.

The previously unimmunized household and sexual contacts after contact with confirmed case of HAV infection should immediately receive two dose schedule of hepatitis A vaccine. Newborn infants born to HAV-infected mother should receive Ig (0.02 mL/kg) if mother's symptoms started 2 weeks before and 1 week after delivery. School exposure does not warrant prophylaxis unless transmission within school is documented. However, unimmunized close contacts of an index case need prophylaxis.

Immunosuppressed patients show a reduced immune response and waning protective level to inactivated hepatitis A vaccines. Most individuals with compensated chronic liver disease who do not receive immunosuppressive therapy achieve similar seroprotection rates as those in healthy subjects. However, anti-HAV antibody levels following immunization are reduced, proportional to the degree of liver failure. Anti-HAV antibody seroconversion rates in HIV-infected individuals ranged from 52% to 94%.

**Outbreaks** During outbreaks in addition to general and contact precautions, exclusion of cases from childcare center, schools or workplaces especially those who work as food handlers for at least 1 week after onset of symptoms should be done. Prevention of further spread by isolation of source of infection and improving sanitation and personal hygiene should be contemplated. Prophylaxis for pre-exposure and postexposure with either vaccine or Ig has shown to be beneficial. Recommendations for hepatitis A vaccination in outbreak situations depend on the epidemiologic features of hepatitis A in the community and the feasibility of rapidly implementing a widespread vaccination program. The use of a single dose regimen of hepatitis A vaccine to control community-wide outbreaks has been most successful in small self-contained communities, when vaccination was started early in the course of the outbreak, and when high coverage of multiple age-cohorts was achieved. Vaccination efforts should be supplemented with health education and improved sanitation.

### PASSIVE PROPHYLAXIS

Passive prophylaxis with Ig against HAV infection is well documented and can be used for both pre- and postexposure prophylaxis. However the duration of protection is limited to approximately 1–2 months and 3–5 months following

administration of IgG at doses of 0.02 mL/kg and 0.06 mL/kg body weight, respectively. Prophylaxis is achieved within hours of injection and is 80–90% effective when administered before, or no later than 14 days after exposure. The use of Ig for protection against HAV has declined because of insufficient concentrations of anti-HAV IgG in nonspecific Ig preparations, the high cost of specific HAV IgG preparations, the limited duration of protection following passive IgG prophylaxis against HAV infection, and because controlled trial showed no significant difference in terms of protection against symptomatic and asymptomatic hepatitis A infection when either an IgG preparation or a hepatitis A vaccine was administered to contacts of confirmed hepatitis A.

### IN A NUTSHELL

1. India has been hyperendemic for HAV infection with nearly 90% of adolescents, adults, and most children were found seropositive.
2. Epidemiology of HAV infection is changing in India.
3. Recent studies have indicated a shift in epidemiology with significant decrease in seropositivity of HAV infection over the past decade.
4. In India, HAV has shown to be associated with up to 50% of all cases of fulminant hepatic failure (FHF) in children with high case fatality rate.
5. Highly efficacious and safe inactivated and live-attenuated hepatitis A vaccines are available in India.
6. Immunization generates long-lasting, possibly life-long, protection against HAV infection in children as well as in adults.
7. Passive prophylaxis with Igs against HAV infection is well documented and can be used for both pre- and postexposure prophylaxis.

## Chapter 23.21

# Meningococcal Vaccine

Jaydeep Choudhury

Meningococcal disease is caused by *Neisseria meningitidis*, which is a gram-negative diplococcus bacterium. The bacteria appear as paired bean with flat surfaces facing each other and enclosed in a polysaccharide capsule. There are 13 serological variants of *Neisseria meningitidis* (A, B, C, 29E, H I, K L, W135, X, Y and Z). Serotypes A, B, C, W135 and Y are responsible for invasive disease. Humans are the sole natural reservoir. Meningococcal infections are though rare but often serious result in fatality if the treatment is not started early. It is an important cause of meningitis and sepsis, particularly in children below 5 years. *Neisseria meningitidis* spreads through infected droplets or through contact with respiratory secretions. The disease spectrum includes meningitis, pneumonia, septicemia, myocarditis and arthritis. Rarely does it present with shock, known as Waterhouse-Friderichsen syndrome.

There is low incidence of meningococcal disease in India, hence childhood vaccination with meningococcal vaccine is not routinely recommended. According to a recent Indian review, meningococcal meningitis constitutes 1.5–3.3% of all acute hospital admissions in children. It is indeed the third most common cause of bacterial meningitis amongst Indian children less than 5 years of age. Septicemia due to meningococcal infection is responsible for 2.8% of all hospital admissions. While there is low incidence of endemic disease, frequent outbreaks of meningococcal meningitis, particularly of type A, are noted mainly from the temperate northern than tropical southern regions of the country. These outbreaks occur mostly during the dry and cold season, usually during postmonsoon season. There are two peaks of the disease encountered globally that include young children around 2 years and adolescents.

## MENINGOCOCCAL VACCINES

### Meningococcal Polysaccharide Vaccine (MPSV)

Polysaccharide vaccine is available against serogroups A, C, W135 and Y. The vaccines are either bivalent (A and C) or quadrivalent (A, C, Y and W135). These vaccines can be given only in children above 2 years of age. These vaccines are safe. Most common side effects are local pain and redness at site of injection.

**Immunogenicity and efficacy** While the serogroup A polysaccharide is capable of inducing antibodies in some children as young as 3 months, the serogroup C is poorly immunogenic in children less than 2 years. Both these serogroups (A and C) have good immunogenicity and the good clinical efficacy among children 5 years of age or older and adults. Serogroup Y and W-135 polysaccharides are safe and immunogenic in older children and adults.

### Meningococcal Conjugate Vaccines

The polysaccharide vaccines elicit poor immunological response and they are not T-cell dependent, hence they do not produce good immunological memory. These shortcomings of polysaccharide vaccines led to development of polysaccharide-protein conjugate vaccines. Two types of meningococcal conjugate vaccines (MCVs) are licensed in India—a quadrivalent vaccine Menactra® from Sanofi Pasteur and another a monovalent serogroup A vaccine from

Serum Institute of India (SII). The latter is not available in private market in India. These vaccines are T-cell dependent and more immunogenic. They also exhibit herd effect through protection from nasopharyngeal carriage. They can also be given to children below 2 years of age. The conjugate meningococcal vaccines are heat labile and should be stored in cold chain at 2–8°C.

### Quadrivalent Meningococcal Conjugate Vaccine

It is a polysaccharide-protein conjugate vaccine covering serogroups A, C, W135 and Y. It uses diphtheria toxin as carrier protein. It is administered as a 0.5 mL dose intramuscular injection. It is licensed in India for use amongst individuals aging 2 years or above. A single dose is recommended in the age group of 2 years through 55 years whereas the vaccine is licensed in the United States to be used above 9 months of age. Two doses are recommended 3 months apart in children between ages of 9 months and 23 months.

It has got minor side effects like local pain, induration, redness and swelling. Guillain-Barré syndrome has been reported as possible, but unproven risk in some adolescents following vaccination with quadrivalent meningococcal conjugate vaccines. There is possibility of interference of immune response with 13 valent conjugate pneumococcal vaccine (PCV 13). In children where both the vaccines are recommended, PCV 13 should be administered first and meningococcal conjugate vaccines should be given after a gap of 4 weeks.

### Monovalent Meningococcal Conjugate Vaccine

Monovalent polysaccharide-protein conjugate vaccine covers serogroup A. Tetanus toxoid is used as carrier protein. The vaccine is recommended as single 0.5 mL IM to individuals 1–29 years of age. The vaccine has been found to be very effective in Africa where meningococcal A disease is prevalent. The vaccine is also very safe.

## INDIAN ACADEMY OF PEDIATRICS RECOMMENDATIONS

The Academy has not recommended routine use of meningococcal vaccine owing to very low incidence of the disease. It is recommended only for certain high-risk conditions and situations as detailed below in children aged 2 years or more (3 months or older if risk of meningococcal disease is high, e.g., outbreaks/close household contact). Conjugate vaccines should be preferred over polysaccharide vaccines due to superior immunogenicity and their potential for inducing herd effect, particularly in children less than 2 years of age.

Meningococcal vaccine should be offered to the following high-risk groups:

- Immunocompromised individuals like people suffering from human immunodeficiency virus (HIV), complement deficiency, individuals with B-cell defects, etc.
- Children with functional/anatomic asplenia/hyposplenia (vaccination should ideally be done 2 weeks prior to splenectomy)
- Students staying in boarding hostels or studying abroad
- Hajj pilgrims
- In outbreak situations
- Laboratory personnel and health-care workers
- Adjunct to chemoprophylaxis, in close contacts of patients with meningococcal disease
- Travellers to countries in the African meningitis belt.

**IN A NUTSHELL**

1. *Neisseria meningitides* has got 13 different serogroups, of which only A, B, C, W135 and Y serotypes are responsible for invasive disease (meningitis, pneumonia, septicemia, myocarditis and arthritis).
2. The overall burden of endemic meningococcal disease in India is very low, hence routine childhood vaccination is not recommended.
3. Outbreaks of group A meningococcal meningitis are regularly reported from many northern states of India.
4. Two types of meningococcal vaccines have been developed, polysaccharide and conjugate vaccine.
5. Polysaccharide vaccines cannot be given to children below 2 years of age be given only in children above 2 years of age.
6. The polysaccharide-protein conjugate vaccines are T-cell dependent and more immunogenic and can be given in children below 2 years of age.

## Chapter 23.22

# Seasonal and Pandemic Influenza Vaccines

*Shobha Broor*

The influenza viruses types A and B are important global causative agents of flu, causing annual epidemics which are associated with excess hospitalizations and mortality, particularly among children and the elderly and those having comorbidities such as, cardiopulmonary and metabolic diseases and immunodeficiency. Prevention of infection by influenza virus by means of vaccination is recommended for all of these populations and their contacts. In the United States an estimated 25–50 million cases of influenza occur annually and resulting in approximately 225,000 hospitalization. Further this results in 30,000–70,000 excess deaths/year. In developed countries, influenza associated hospitalization rates per 100,000 have varied from 78 to 108 in the United States to 190 in the United Kingdom.

The exact disease burden for influenza for India is not known but approximately 0.6 million hospitalizations related to influenza are expected in India. Among children less than 5 years old, influenza-related hospitalization rates are highest in those, less than 1 year of age. Influenza disease burden in India is comparable to other parts of the world. In a recent study, among children aged less than 5 years, estimated influenza associated hospitalization rate was 93 per 100,000 children in Ballabgarh and 350 per 100,000 in Vadu.

## EPIDEMIOLOGY OF INFLUENZA

### Influenza Epidemics

Influenza outbreaks have a well-defined seasonality. Influenza A outbreaks typically begin abruptly, peak over a 2–3-week period, and last for 2–3 months. In most outbreaks, the earliest indication of influenza activity is an increase in febrile respiratory illnesses in children, followed by increases in influenza-like illnesses in adults. One factor that may influence which influenza strains will predominate during an influenza season is the seroprotection rate among children during the preceding season. In a study in which children and adults were tested for antibodies to locally circulating influenza strains during three consecutive influenza seasons (2006–2007, 2007–2008 and 2008–2009), the lowest rates of seroprotection in children (but not in adults) coincided with the dominant influenza subtype during the following winter epidemic. The protection rate in children is important for shaping future epidemics because children are prolific disseminators of respiratory virus infections. Most outbreaks have attack rates of 10–20% in the general population, but rates can exceed 50% in pandemics.

### Seasonality of Influenza Epidemics

In temperate regions of the Northern and Southern hemispheres, influenza peaks during winter season (which occur at different times of the year) and these annual winter epidemics are associated with excess deaths from influenza and pneumonia. Although they occur in distinct periods of the year, influenza strains circulating in the two hemispheres are not independent of each other, and strains circulating in one hemisphere will inevitably spread to the other hemisphere during the next season. The pattern of influenza is different in tropical and subtropical areas, with year-round

circulation in some areas and biannual peaks in others. It remains unclear whether tropical regions where influenza circulation is reported throughout the year serve as reservoir for the epidemics in both hemispheres. Recent studies from Bangladesh, Cambodia, India, Laos, Myanmar, Singapore, Thailand and Vietnam outlined an important role of regular influenza surveillance. Influenza activity peaked between June/July and October in 7 out of 10 countries, 3 of which showed a second peak in December to February. In Bangladesh, Cambodia, India, the Lao People's Democratic Republic, the Philippines, Thailand and Vietnam, more than 60% of cumulative proportion of specimens positive for influenza were from June to November from 2006 to 2011. Countries closer to the equator (Indonesia, Malaysia and Singapore) had year-round circulation without discrete peaks. Since the peak of influenza circulation coincides with rainfall during July to October for most countries in Southeast Asia, influenza vaccination prior to monsoon season in some countries in the tropical Asian region in the northern hemisphere may be more beneficial.

### Pandemics of Influenza

Pandemics of influenza occur unpredictably and relatively infrequently, but they are important as they result in the global circulation of a new influenza A virus subtype that can lead to substantially increased morbidity and mortality in all age groups. In June 2009, the World Health Organization (WHO) raised its pandemic alert level to the highest level, phase 6, indicating widespread community transmission in at least two continents. The pandemic was declared to be over in August 2010. The 2009 to 2010 H1N1 influenza A pandemic was caused by an A/H1N1 virus that had not been recognized previously in pigs or humans. This strain represented a genetic reassortment of swine, human and avian strains of influenza. Pandemic H1N1 influenza A infections were uncommon in persons older than 65 years, possibly as a result of pre-existing immunity against antigenically similar influenza viruses that circulated prior to 1957.

Recent H1N1 pandemic of 2009 has estimated 285,000 deaths globally. It is predicted that Southeast Asia and Africa had the highest mortality and 59% of all deaths may have occurred on these two continents, which are home to 38% of the world's population. Increased morbidity and mortality among children was observed with 2009 pandemic H1N1 influenza virus as compared to seasonal influenza. Although the majority of reported deaths occurred in individuals with underlying comorbidities, up to one-third of hospitalized patients had no underlying chronic illness. Higher mortality and severe illness was also seen with pandemic H1N1 infection in pregnant women. In pandemic influenza unlike seasonal influenza where elderly are more affected, a shift in the age distribution towards children is seen. Data from three recent influenza pandemics show that school-aged children had the highest disease rates and may serve as a key source of transmission to adults.

### Seasonal and Pandemic Influenza in India

A laboratory-based virological surveillance network of influenza viruses has been setup in geographically distinct regions in northern, central, southern and eastern India by Indian Council of Medical Research. Extensive surveillance carried out in India reveals a major peak of influenza which coincides with rainy season in tropical region of India in Pune, Delhi, Kolkata and Chennai and a minor peak in winter, though some level of circulation has been observed throughout the year. In contrast, influenza circulation peaks in winter in Srinagar, similar to what has been observed for temperate regions. The influenza surveillance network has identified varying seasonality, with cocirculation of all subtypes.

## INFLUENZA VACCINES

Influenza vaccines have two different formulations one for Northern hemisphere and second for Southern hemisphere. The vaccine strains may be similar for both formulations or different depending on the circulating strains. Influenza vaccines are modified annually, based on WHO recommendations. Annual update of vaccine strains is essential for vaccines to be effective due to constant antigenic changes in influenza viruses. Since 1973, WHO has provided recommendation for the composition of influenza vaccines based on the information provided by WHO Global Influenza Surveillance Network (GISN). Twice annually WHO specialist meet in February and September to consider the epidemiological data collected during the previous year and to recommend which influenza strains will be most likely to cause epidemics the following year and should therefore be part of the vaccine to be used for Northern hemisphere and Southern hemisphere formulations. High yield candidate vaccine strains are then developed by reassortment by WHO collaborating centers (CCs). These are then sent to CCs which carry out complete identification of the viruses, with detailed antigenic descriptions.

### Types of Influenza Vaccines

**Killed vaccines** Trivalent inactivated influenza vaccine (TIV), this terminology has now been replaced with inactivated influenza vaccine (IIV) which can be egg or cell-culture based. This included IIV3 (trivalent vaccine) and IIV4 (quadrivalent vaccine). Cell-culture-based vaccine is also referred as ccIIV/ccIIV3. In recent years a recombinant hemagglutinin (HA) vaccine has also been licensed which is called trivalent recombinant influenza vaccine (RIV3).

**Live vaccines** Live-attenuated influenza vaccine (LAIV) which can be trivalent LAIV3 or quadrivalent LAIV4.

### Inactivated Influenza Vaccines (IIV3/IIV4)

Inactivated vaccines are the primary means of preventing influenza infection, due to the vast experience of their use worldwide. Vaccines made with whole viruses induce good levels of immunogenicity, but have greater reactogenicity, and are known to cause fever in children and, therefore, are not indicated for this age group. Split vaccines are made either from fragmented or subunit viruses; these have a good safety profile with the first being more immunogenic than the second and both are recommended for children under 12 years. Virosome vaccines are inactivated vaccines in which the HA and neuraminidase (NA) influenza virus surface antigens are incorporated into virus-like particles that have an adjuvant role. This type of vaccine offers similar immunogenicity and safety to other vaccines.

Current formulations of these vaccines (IIV3) contain three influenza virus strains, i.e., (1) influenza A subtypes H1N1 and (2) H3N2 and (3) influenza B. The strains to be included in the vaccine are selected annually on the basis of the viruses anticipated to be circulating during the upcoming influenza season. Quadrivalent IIV (IIV4) vaccine has two influenza B strains, (1) Victoria and (2) Yamagata, lineage. Hemagglutinin is the main immunogen in IIVs. Virus strains to be included in IIV are grown in embryonated hen eggs, inactivated and then (in most instances) preserved with thimerosal (1:10,000).

### Efficacy and Immunogenicity

The results of clinical trials investigating the efficacy of the IIV vary greatly, depending upon age group, season, vaccine strain match with circulating strain and endpoint of analysis of efficacy. In

general, efficacy against confirmed influenza virus infection varies from 31% to 91% and is not uniform for the subtypes. Protective efficacy for acute otitis media (AMO) is more variable, being reported as absent by some authors and up to 36% by others. IIVs are less effective in children and elderly, the two populations at most risk of developing severe disease. Other limitations of IIVs include extended production times (which has led to vaccine shortages in the past) and decreased efficacy against influenza viral strains that are antigenically different from those contained in the vaccine.

### Safety and Adverse Events

Inactivated influenza vaccines are very safe in children as seen over last many years in many populations based studies. The most common side effects seen with IIV administration are soreness at the injection site and fever. Fever, is more common in children less than 2 years of age (10–35% of recipients), and usually occurs within 6–24 hours after immunization. Mild systemic symptoms such as nausea, lethargy, headache, muscle aches and chills are also reported in some cases.

During the *swine flu* vaccine program in 1976, an increase in the number of cases of Guillain-Barré syndrome (GBS) was reported in adults within 10 weeks after immunization. Additional investigations have revealed that there may be a slight increase in the risk of GBS (approximately 1 additional case of GBS per 1 million vaccine recipients) among adults after influenza immunization, at least in some years. The Institute of Medicine evaluated the association of demyelinating diseases and influenza vaccine and concluded that there is no evidence bearing on a causal relationship between influenza vaccines and demyelinating neurologic disorders in children 6–23 months of age.

Even in with human immunodeficiency virus (HIV)-affected individuals, most experts believe that the benefits of influenza immunization with IIV far outweigh the risks in children with HIV infection.

Because influenza vaccine is grown in embryonated hen eggs, children demonstrating anaphylactic reactions to chicken or egg proteins may rarely experience a similar reaction to influenza vaccine and therefore should not be given IIV unless they undergo desensitization. IIV containing thimerosal should not be given to individuals with hypersensitivity to thimerosal.

### Live-attenuated Influenza Vaccine

Live-attenuated, cold-adapted, trivalent influenza vaccine has been developed by repeated passages of influenza viruses at lower temperature. The cold adapted strains grow better at 25°C and their replication is restricted at 38°C–39°C. The LAIV strains for vaccine for each year are made by reassortment with these cold adapted master strains and grown in eggs to a high titer. LAIV is given by intranasal route 0.25 mL in each nostril using an accuspray device and is more effective than IIV in children. LAIV is thus a good and effective approach for prevention of influenza in children. In India Serum Institute of India (SII) is making trivalent LAIV using Russian virus master strains. In the United States of America Medimmune makes both trivalent and quadrivalent LAIV. Each 0.5 mL dose of trivalent vaccine contains approximately 10<sup>7</sup> tissue culture infectivity doses of influenza strains A subtype H1N1, A subtype H3N2, and B. Children younger than 9 years of age being immunized against influenza for the first time should receive two doses of LAIV given 4–6 weeks apart before the start of the influenza season.

**Efficacy** Efficacy of LAIV in various studies varies from 26% to 93%. Vaccine efficacy against influenza A (H3N2) and B outbreaks has

shown to be greater than 80% efficacious in preventing influenza illness in a multicenter trial of FluMist in pediatric population in the United States.

**Safety** Live-attenuated influenza vaccine has been found to be very safe and no reversion to virulent phenotype has been reported. Side effects in children can include runny nose, headache, wheezing, vomiting, muscle aches and fever. Studies of transmission of LAIV strains to nonimmunized contacts have failed to show transmission as vaccine virus is shed for shorter duration and smaller quantity.

### Choice of Influenza Vaccine

The choice of vaccine for an individual child depends upon age and risk factors for severe or complicated influenza. Persons at risk for severe complications of influenza are shown in **Table 1**. IIV is indicated for children older than or equal to 6 months, including those who cannot receive LAIV. The following groups should receive IIV rather than LAIV:

- Children older than or equal to 6 months through 23 months of age
- Children aged 2 years through 4 years who have asthma or who have had a wheezing episode noted in the medical record within the past 12 months, or for whom parents report that a health-care provider stated that they had wheezing or asthma within the last 12 months
- Children (of any age) with asthma
- Children aged 2 years through 17 years who are receiving aspirin or aspirin-containing products
- Children who have experienced allergic reaction to vaccine or any of its component to a previous dose of LAIV
- Children with medical conditions that increase the risk for severe or complicated influenza infection
- Children who are close contacts of severely immunocompromised individuals (e.g., hematopoietic stem cell transplant recipients).

Children older than 2 years who are not in one of the categories listed above may receive either IIV or LAIV. According to several studies in children, LAIV may be more efficacious than IIV, and provides better immunity against mismatched strains, may provide

immediate protection during an outbreak, may provide better T-cell responses and may provide longer-standing protection than IIV. Compared with IIV, LAIV also provided better protection in preventing culture-confirmed influenza in children. A randomized controlled trial conducted among 7,852 children aged 6–59 months demonstrated a 55% reduction in culture-confirmed influenza among children who received LAIV compared with those who received IIV. LAIV efficacy was higher than that of IIV against both antigenically drifted and well-matched influenza viruses. Side effects appear to be similar for LAIV and IIV. **Table 2** provides a comparative analysis of LAIV and IIV for seasonal influenza while **Table 3** lists the available and licensed influenza vaccines in India.

### INFLUENZA VACCINATION RECOMMENDATIONS

Both *Government of India* (GoI) and *Indian Academy of Pediatrics* (IAP) have not recommended universal immunization of healthy children against influenza. IAP has recommended seasonal influenza vaccine, IIV only for the category of *high-risk children*, which includes the following:

- Chronic cardiac, pulmonary (excluding asthma), hematologic and renal (including nephritic syndrome) condition, chronic liver diseases and diabetes mellitus
- Congenital or acquired immunodeficiency (including HIV infection)
- Children on long-term salicylates therapy
- Laboratory personnel and health-care workers.

*Advisory Committee on Immunization Practices* [ACIP; a branch of the United States Centers for Disease Control and Prevention (CDC)] recommends routine annual influenza vaccination for all persons aged older than or equal to 6 months who do not have contraindications.

### Best Time to Vaccinate

Vaccination optimally should occur before onset of influenza activity in the community. Since in India, Influenza peaks mainly are seen during rainy season, vaccination should be offered before onset of monsoon in the country. The best time for offering vaccine for individuals residing in southern states would be just before the onset of rainy season, i.e., before October while for rest of the country, it should be before June. According to WHO classification, the recommendations on vaccine formulation for India strongly favor the *Southern hemisphere vaccine* rather than *Northern hemisphere*. However, since there is a lag period of 6 months between issuance of recommendations on constitution of the vaccine for a particular hemisphere and production and availability of vaccine in the market, it is advisable to use the vaccine available with the newest strain rather than delaying the vaccination.

### Dosage and Schedule

Children aged 6 months through 8 years require two doses of influenza vaccine (administered greater than or equal to 4 weeks apart) during their first season of vaccination to optimize immune response. This is truer for influenza B as children who received one dose had a lower response as compared to children who had received two doses in the prior season. In determining the appropriate number of doses, previous receipt of vaccine containing 2009 influenza A (H1N1) pandemic antigen (included in monovalent pandemic vaccine during 2009–10 and in seasonal influenza vaccines since the 2010–11 season) also should be considered. In addition, because the strains contained in the 2014–15 seasonal influenza vaccines are identical to those contained in the 2013–14 vaccines, only one dose is required for any child aged 6 months through 8 years who previously received more than one dose of 2013–14 seasonal influenza vaccine (**Flow chart 1**).

**Table 1** Groups at high-risk for influenza complications

- Children 6–59 months of age
- All persons 50 years of age and older
- Anyone with chronic pulmonary (including asthma) or cardiovascular (except isolated hypertension), renal, hepatic, neurological, hematologic, or metabolic disorders (including diabetes mellitus)
- Persons who have immunosuppression, including immunosuppression caused by medications or HIV infection
- Women who are or will be pregnant during the influenza season
- Children (6 months through 18 years) receiving long-term aspirin therapy and who might be at risk for experiencing Reye's syndrome after influenza virus infection
- Residents of nursing homes and other long-term care facilities
- Persons who are morbidly obese (BMI  $\geq 40$ )

#### People who live with or care for those at highest risk

- Health-care personnel
- Household contacts (including children) and caregivers of children younger than 5 years (i.e., prior to the 5th birthday) and adults 50 years of age and older—particular emphasis on vaccinating contacts of children younger than 6 months
- Household contacts (including children) and caregivers of persons with medical conditions that put them at higher risk for severe complications from influenza

**Abbreviations:** HIV, human immunodeficiency virus; BMI, body mass index.

**Table 2** Comparison of live-attenuated influenza vaccine (LAIV) with inactivated influenza vaccine (IIV) for seasonal influenza

	LAIV	IIV
Route of administration	Intranasal spray	Intramuscular injection**
Type of vaccine	Live attenuated	Killed virus
Number of included virus strains	Three/four (two influenza A, one/two influenza B)	Three/four (two influenza A, one/two influenza B)
Vaccine virus strains updated	Annually*	Annually*
Frequency of administration	Annually	Annually
Approved age	Persons aged > 2 years to 49 years	Persons aged ≥ 6 months
Interval between two doses recommended for children aged ≥ 6 months to 8 years who require two doses	≥ 4 weeks	≥ 4 weeks
Can be administered simultaneously with other vaccines	Yes	Yes
If not administered simultaneously, can be administered within 4 weeks of another live vaccine	Prudent to space ≥ 4 weeks apart	Yes
If not administered simultaneously, can be administered within 4 weeks of an inactivated vaccine	Yes	Yes

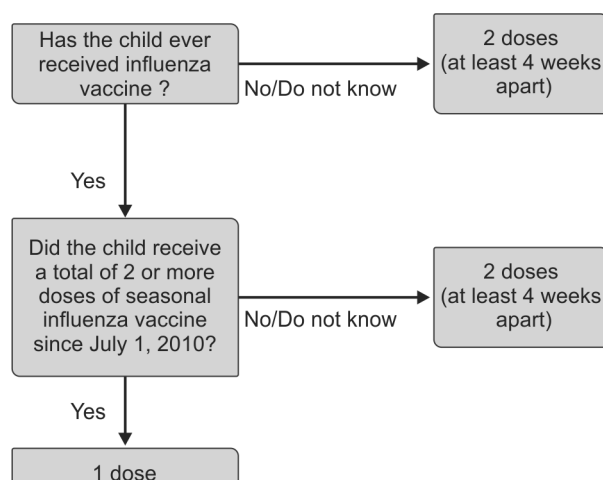

\* Every year World Health Organization (WHO) decides regarding which virus strains will be included in the vaccine for the upcoming influenza season. Even in years in which the vaccine composition is the same as the previous season, annual vaccination is necessary since immunity wanes.

\*\* For adults and older children, the recommended site of vaccination is the deltoid muscle. The preferred site for infants and young children is the anterolateral aspect of the thigh.

**Flow chart 1** Algorithm for influenza dose in children from 6 months to 8 years of age

### Influenza Vaccination of Persons with a History of Egg Allergy

With the exceptions of RIV3 [(FluBlok), Protein Sciences] and cell-culture-based IIV [ccIIV3 (Flucelvax), Novartis], currently available influenza vaccines are prepared by propagation of virus in embryonated chicken eggs. However, a review of published data has shown that severe allergic reactions to egg-based influenza vaccines are unlikely. History of mild egg allergy is not an absolute contraindication for IIV/LAIV; however, they should be used with caution in these individuals. On the other hand, a previous severe allergic reaction to influenza vaccine, regardless of the component suspected of being responsible for the reaction, is a contraindication to future receipt of the vaccine.

### Influenza Immunization of Pregnant Women

Influenza may cause more severe illness in pregnant women than in women who are not pregnant. Changes in the immune system, heart and lungs during pregnancy make pregnant women more

prone to severe illness. Even deaths due to influenza are more common in pregnant women; pregnant woman with influenza can also have adverse effect on pregnancy outcomes in terms of prematurity, low birth for term babies. Influenza vaccination of pregnant mothers with killed influenza vaccine has been shown to be safe and provides protection to both mother and newborn baby up to 6 months. Live influenza vaccine however should not be given to pregnant mothers.

### IN A NUTSHELL

1. Influenza virus infection is associated with increased rates of hospitalization in children particularly in those younger than 2 years.
2. Immunization is the major means of influenza prevention.
3. Two types of influenza vaccines are available: (1) IIV, which is administered intramuscularly and (2) LAIV, which is administered intranasally.
4. Both the killed and live vaccines are safe and efficacious.
5. Routine vaccination against influenza to healthy children is not recommended in India by both Gol and IAP.
6. The choice of vaccine for an individual child depends upon age and risk factors for severe or complicated influenza. IIV is indicated for children older than or equal to 6 months, including those who cannot receive LAIV.
7. Individuals older than 2 years and younger than 50 years who are not among of the categories listed above may receive either TIV or LAIV. As LAIV has broader and more durable immunity if available should be used in these groups.
8. Annual immunization is necessary even if the previous season's vaccine contained one or more of the antigens to be administered in the current season because immunity declines during the year following vaccination.
9. Vaccine with the newest strain should be preferred at the time of vaccination. The best time to vaccinate is before onset of monsoon in India.
10. For individuals residing in southern states, the best time would be just before the onset of rainy season, i.e., before October while for rest of the country, it should be before June.

## Chapter 23.23

# Human Papillomavirus Vaccines

Srinivas G Kasi

Genital infection with human papillomavirus (HPV) is a necessary cause of cervical cancer and an important etiologic agent for other anogenital cancers (anus, vulva, vagina and penis) and head and neck cancers. HPV types 16 and 18 are responsible for about 70% of all cervical cancer cases worldwide. It is estimated that cervical cancer affects approximately 527,624 women each year, of whom 444,546 (80%) live in developing countries.

Cervical cancer in India ranks as the second most frequent cancer among women. About 7.9% of women in the general population are estimated to harbor cervical HPV infection at a given time, and 84.1% of invasive cervical cancers are attributed to HPVs 16 or 18. Current estimates indicate that every year, in India, more than 100,000 women are diagnosed with cervical cancer with a crude incidence rate of 20.2 and more than half of them die from the disease, with a crude mortality rate of 11.1. This is the highest in the world.

## VIROLOGY

The HPVs are a family of nonenveloped viruses that belong to the family Papillomaviridae. They have an icosahedral capsid of approximately 60 nm in diameter. L1 is the major capsid protein while L2 is the other capsid protein. The early proteins (E1, E2, E4, E5, E6 and E7) regulate viral transcription and genome replication. There are over 100 HPV genotypes with distinct tissue tropism for squamous epithelia of either cutaneous or mucosal tissue regions. Mucosal infections of HPV fall in two groups: (1) low-risk type viruses (mainly HPV6 and 11), which induce genital warts and (2) high-risk types (HPV16, 18 and others), which lead to malignancies such as cervical carcinoma, anal cancer and oropharyngeal carcinoma.

While most HPV infections are transient, about 1% of individuals infected with HPV types 6 and 11, develop clinically significant genital warts. Approximately 70% of new infections resolve within 1 year and 91% within 2 years. About 25% of all women infected with high-risk HPV develop cervical intraepithelial neoplasia (CIN) and less than 1% develops invasive cervical cancer.

## PATHOGENESIS

Microabrasions that occur at the cervicovaginal junction during penetrative or nonpenetrative sexual encounter expose the basal undifferentiated keratinocyte cells. The virion gets attached to these cells by binding to its receptor, heparan sulfate proteoglycans (HSPGs) by a L1 dependent mechanism, gets internalized by endocytic mechanisms and delivers the genome to the host nucleus. In the basal cells the viral early genes are expressed and the genome is replicated at approximately 100 copies/cell. As the basal keratinocytes mature, they move up the epithelial layers, where the late proteins get expressed. In the superficial layers viral particles are assembled and released into the cervical lumen. Thus, in the initial stages of infection, the host immune system remains largely unaware of the ongoing infection.

Risk factors for development of cervical cancer include infection with certain oncogenic types of HPVs, sexual intercourse at an early age, multiple sexual partners, multiparity, long-term oral contraceptive use, tobacco smoking and low socioeconomic status.

## HUMAN PAPILLOMAVIRUS VACCINES

The two presently available HPV vaccines in India are produced by recombinant technology. The L1 gene of the HPV is inserted into a host (*baculovirus* or *Saccharomyces cerevisiae*), which results in the production of large quantities of L1 proteins which undergo self-assembly into virus-like particles (VLPs) that resemble the outer capsid of the whole virus. The HPV VLPs do not contain viral deoxyribonucleic acid (DNA) and are therefore noninfectious and nononcogenic, but elicit a strong immune response comparable to the intact virion.

Cervarix<sup>®</sup>, manufactured by GSK, is a bivalent vaccine containing the VLPs of types 16 and 18 and Gardasil<sup>®</sup>, manufactured by Merck and Co, United States of America, is a quadrivalent vaccine containing the VLPs of types 6, 11, 16 and 18. Both vaccines are preservative free (**Table 1**).

For vaccine licensure, the World Health Organization (WHO) has recommended the endpoints of CIN2/3 or adenocarcinoma in situ (AIS) as a proxy for cervical cancer as these endpoints can be studied feasibly considering the long incubation period of cervical cancer. In children or young adolescents, bridging studies are conducted by comparing antibody responses in younger persons with those in the women for whom data on the clinical endpoint of CIN2/3 or AIS are available.

## Vaccine Indications, Schedule and Dosage

Cervarix<sup>®</sup> is indicated for the prevention of premalignant lesions of the cervix, vagina and vulva and cervical cancer causally related to certain oncogenic HPV types. Gardasil<sup>®</sup> is indicated for the prevention of premalignant lesions of the cervix, vagina and vulva and cervical cancer causally related to certain oncogenic HPV types and genital warts causally linked to certain HPV types. In addition, Gardasil<sup>®</sup> is indicated in certain countries for the prevention of external genital warts and anal intraepithelial neoplasia in males 9–26 years of age.

The dose for both vaccines is 0.5 mL intramuscular in deltoid. Both vaccines are intended to be administered to females before the onset of sexual activity, that is, before first exposure to HPV infection. The recommended age for initiation of vaccination is 10–12 years. Presently, in India, the vaccines are permitted for usage up to the age of 45 years.

According to 2014 recommendations of IAP-ACVIP and the WHO, two doses of HPV vaccine are advised for 9–14 years old girls, the minimum interval between doses should be 6 months. The interval between the first and second dose may be extended up to 12 months, should this facilitate administration say in school settings. For girls, primed before the age of 15 years, even if older at the time of boosting (second dose), a two-dose schedule will be applicable. For girls 15 years and older, a 3 dose schedule for both vaccines is recommended. For the quadrivalent human papillomavirus (QHPV), the 3 dose schedule consists of three doses at 0, 2 and 6 months (minimum interval between first and second dose of 4 weeks and second and third dose, 12 weeks) and 0, 1 and 6 months for the bivalent vaccine. However, for immunocompromised individuals, including those known to be HIV-infected, the three dose schedule is recommended irrespective of age. HPV vaccines can be given simultaneously with other vaccines such as hepatitis B and Tdap. Since syncope following any vaccine is common in adolescents, the vaccine should be administered in a sitting/lying down position and post vaccination the patient should be observed for 15 minutes.

The new recommendations for a 2-dose schedule in 9–14 years old have been made on the basis of data generated from randomised and non-randomised comparison of 2 doses in the 9–14 years old versus 3 doses in 9–14 years old and young women. These studies

**Table 1** Comparison of available human papilloma virus (HPV) vaccines

	<i>Gardasil®</i>	<i>Cervarix®</i>
Manufacturer	Merck and Co, United States of America	GSK, Belgium
VLP types	6, 11, 16 and 18	16 and 18
Antigen content	HPV6: 20 mcg HPV11, 16, 18: 40 mcg each	HPV16, 18: 20 mcg each
Production system	<i>Saccharomyces cerevisiae</i>	<i>Baculovirus</i>
Adjuvant	Proprietary aluminum hydroxyphosphate sulfate (225 µg)	Proprietary aluminum hydroxide (500 µg) plus 50 µg 3-deacylated monophosphoryl lipid A (GSK AS04 adjuvant)
Route	Intramuscular	Intramuscular
Schedule	0–2–6 months	0–1–6 months
Target age group	9–45 years	10–45 years
Approved indications	<ul style="list-style-type: none"> <li>• Prevention of cervical cancers and precancers</li> <li>• Vulvar and vaginal cancers and precancers</li> <li>• Anal cancers and precancers</li> <li>• External genital warts</li> <li>• Approved in males 9–26 years for prevention of anal cancers and precancers</li> <li>• All caused by HPV16 and 18</li> </ul>	<ul style="list-style-type: none"> <li>• Prevention of cervical cancers and precancers</li> <li>• Vulvar and vaginal cancers and precancers (In European only)</li> <li>• All caused by HPV 16 and 18</li> </ul>

®Tradenames

have shown that seroconversion and seropositivity were non-inferior or inconclusive at all-time points in the 2-dose schedule. The 6-month interval resulted in superior GMCs compared with the 2-month interval one month after the last vaccine dose in all the age groups enrolled.

### Protective Mechanism

No immune correlate of protection has been established in the efficacy trials. Existing evidence suggest that neutralizing antibodies are the primary effectors of vaccine induced protection. It is suggested that direct exudation of serum antibodies at sites of trauma is the primary mechanism of protection. High levels of anti-VLP antibodies prevent binding of the virion to the basement membrane, while lower levels prevent transfer of the virion to the keratinocytes.

### Immunogenicity and Duration of Protection

Both vaccines are highly immunogenic with the highest immune responses being observed in young girls aged 9–15 years. The antibody titers against HPV16 and 18 antibodies produced were several folds higher than after natural infection. With the bivalent vaccine, anti-HPV16 and 18 titers remained at high levels for at least 8.4 years with 100% seropositivity maintained, with the quadrivalent vaccine anti-HPV16 titers remained high at least 5 years with 98.8% seropositivity maintained. However, 18 months after first vaccination, anti-HPV18 antibody titers return to the level of natural infection, with a further reduction in seropositivity over time. Since the efficacy has remained undiminished for the QHPV vaccine, the clinical significance of this observation is still to be established.

Immunobridging studies done for both vaccines, in young adolescents, have shown that the neutralizing antibody responses in boys and girls were statistically noninferior and observationally higher than those observed in young females. Noninferiority in boys was demonstrated in another study. In women aged 26–55 years, the immunogenicity of the BHPV was several times higher

than that induced after a natural infection, remained high for the 24 months of follow-up and followed the same kinetics as those observed in young women. For QHPV, in 24–45 years old women, at month 48, 91.5%, 92.0%, 97.4% and 47.9% of vaccinated women were seropositive to HPV 6/11/16/18, respectively. A rapid and strong anamnestic humoral immune response was elicited following a fourth dose of both vaccines.

**Prophylactic efficacy** The prophylactic efficacies of both vaccines have been studied in large phase II and III studies and followed up for 3–5 years. Vaccine efficacies against clinical endpoints of both the vaccines are provided in **Table 2**. Long-term efficacy for both vaccines has been demonstrated across all age groups.

**Cross protection** Immunity to HPV is type-specific. However, HPV16 is phylogenetically related to HPV types 31, 33, 52 and 58 (A9 species) and HPV18 is related to HPV45 (A7 species). For the bivalent vaccine, vaccine efficacy against CIN2+ associated with 12 nonvaccine oncogenic types was 54.0% (34.0–68.4; ATP-E). Individual cross-protection against CIN2+ associated with HPV-31, HPV-33, and HPV-45 was seen in the total vaccinated cohort (TVC). For the quadrivalent vaccine, efficacy against CIN2/3 or AIS during a 3-year follow-up was reported against combined HPV31/45 types (point efficacy: 62%), five combined HPV types, 31/33/45/52/58 (point efficacy: 43%) and 10 combined HPV types, 31/33/35/39/45/51/52/56/58/59 (point efficacy: 38%).

### Vaccine Safety

The safety of bivalent human papillomavirus (BHPV) and QHPV has proven to be excellent in various phase II and III trials both in females and males. With greater than 175 million doses distributed worldwide, the WHO-GAVACS has extensively studied all the potential signals associated with these vaccines and found no causative link with any of them including, GBS, VTE (Guillain-Barré syndrome, venous thromboembolism), seizures, stroke and other severe allergic reactions. Pregnancy outcomes in women

Abbreviations: ATP, according to protocol; PP, per protocol; TVC, total vaccinated cohort; ITT, intention to treat; CIN, cervical intraepithelial neoplasia; VIN, vulvar intraepithelial neoplasia; VaIN, vaginal intraepithelial neoplasia; AIN, anal intraepithelial neoplasia; PIN, penile intraepithelial neoplasia.

inadvertently administered these vaccines during pregnancy, have not resulted in any adverse outcomes above expected rates. No adverse effects have been reported on vaccination during lactation.

## NEW HUMAN PAPILLOMAVIRUS VACCINES

The limited protection against cervical cancer, the high price of the current HPV vaccines which have limited their use in the developing countries having the highest burden of cervical cancer and lack of any therapeutic effect, have been the main drawbacks of the current vaccines. Thus, newer HPV vaccines must address the issues of cost, duration of protection and broader protection. The newer vaccines under study include:

- **Nanovalent vaccine:** A nanovalent vaccine, containing HPV31/33/45/52 and 58, in addition to 6, 11, 16 and 18, code named V503, is in phase III trials. The results of the trials are

still unpublished. It is estimated that this vaccine will raise the protection rate to 90% of squamous cell carcinoma (SCC) worldwide.

- **L2 vaccines:** L2 contains several broad cross-reacting epitopes which elicits antibodies which can neutralize a wide variety of HPV types. However, it is weakly immunogenic. Studies in mice using bacteriophage VLPs and orally administered *Lactobacillus casei* expressing L2 on their surface has given encouraging results.
- **L1 capsomer vaccines:** L1 capsomers can be produced in bacteria, which is cheaper than using the conventional virus and yeast-based systems.
- **Therapeutic vaccines:** The HPV early proteins, E6 and E7 are expressed in all HPV infected cells, and are upregulated in cancer cells. Thus, E6 and E7 have been the choice for therapeutic vaccines. Different strategies are being investigated including the use of live viral or bacterial vectors, peptides, proteins, DNA and dendritic cells. Recently a phase I trial using recombinant HPV16E7 and HPV18E7 established the safety of the product and has progressed to a phase II trial.

## POPULATION IMPACT OF HUMAN PAPILLOMAVIRUS VACCINES

Since its introduction, the HPV vaccines are being used on a large scale in many developed countries and more recently, with global alliance for vaccines and immunizations (GAVI) assistance, in some developing countries. Australia was the first country to introduce the QHPV vaccine in 2007. Between 2007 and 2011, there was 83.4% reduction in inpatient treatment for vulvar/vaginal warts in 15–24-year-old women. There was a significant reduction of high-grade cervical abnormalities in vaccinated women (4.8/1,000 PY in vaccinated vs 6.4/1,000 PY in unvaccinated) within 5 years of implementation, with the greatest vaccine effectiveness (VE) observed for the youngest women.

In Sweden, VE against genital warts was 76% (95% CI = 73–79%) among those who received three doses of the vaccine with their first dose before the age of 20 years, with the highest effectiveness in girls vaccinated before the age of 14 years (effectiveness = 93%, 95% CI = 73–98%). Similar reductions in atypia+ have been reported from Denmark, with the QHPV.

In the United States of America, by 2010, the coverage in 13–19-year group was 32%. With this coverage, a 56% decline in vaccine type HPV prevalence was observed. With GAVI assistance, by 2020, it is estimated that over 30 million girls in more than 40 countries will be vaccinated against HPV.

## THE INDIAN SCENARIO

India accounts for about 25% of all new cervical cancer cases and cervical cancer deaths occurring in the world. According to the 2013 Globocan data, in India, HPV16 and 18 account for 81.3% of all cervical cancer cases. Hence a vaccine containing HPV16 and 18 is bound to be greatly beneficial. However numerous barriers exist in the path towards its acceptance in the National Immunization Program (NIP). Most data on disease burden is obtained from regional cancer registries, while population based data is scanty. Also, due to high cost, HPV vaccines are far beyond the reach of most Indians. Sociocultural issues associated with the HPV vaccine because it targets a sexually transmitted infection and primarily targets female adolescents and young adults are a great barrier.

While routine screening with Pap smear at regular intervals and early treatment of precancerous conditions in the developed countries have been very effective in preventing squamous cervical cancer, these measures are difficult to implement in low-resource settings. Thus, prevention of HPV infections by vaccination has assumed great public health importance.

## IN A NUTSHELL

1. India has the highest rate on cervical cancer cases and deaths in the world.
2. Human papillomavirus is responsible for greater than 99% of cervical cancers and an important etiologic agent for other anogenital cancers (anus, vulva, vagina and penis) and head and neck cancers.
3. Two vaccines against HPV infections are presently available. Cervarix®, manufactured by GSK, is a bivalent vaccine containing the VLPs of types 16 and 18 and Gardasil®, manufactured by Merck and Co, United States of America, is a quadrivalent vaccine containing the VLPs of types 6, 11, 16 and 18.
4. Both vaccines are highly immunogenic with the highest immune responses being observed in young girls aged 9–15 years. The antibody titers against HPV16 and 18 antibodies produced are several folds higher than after natural infection.
5. Both vaccines are highly efficacious in preventing infection with virus types 16 and 18. They are also highly efficacious in preventing precancerous cervical lesions caused by these types.
6. The QHPV vaccine is also highly efficacious in preventing anogenital warts, vulvar and vaginal cancers and precancers.
7. Long-term efficacy for both vaccines has been demonstrated across all age groups.
8. The primary target group in most of the countries recommending HPV vaccination is young adolescent girls between 9 years and 14 years.
9. Data from clinical trials and postmarketing surveillance conducted in several continents have shown both vaccines to be safe.

## Chapter 23.24

## Yellow Fever Vaccine

Parang N Mehta

Yellow fever is a serious disease caused by a virus of the family flaviviridae. It is transmitted to humans by mosquitoes and is maintained in nature in monkeys. Because of this sylvatic cycle, yellow fever cannot be eradicated and preventive measures are important. About 200,000 cases of yellow fever occur annually, mainly in Africa. Cases occur in South and Central America also. Currently, the disease does not occur in Europe and North America and the disease has never occurred in Asia. Yellow fever ranges from subclinical infection to severe hemorrhagic disease with multiple organ system failure. The mortality of yellow fever can be 20–50%.

## YELLOW FEVER VACCINES

The yellow fever virus was isolated in 1927. A killed vaccine could not be made at that time, and an attenuated live vaccine, the 17D vaccine, was developed soon after. This vaccine has been in use for almost 80 years now and has been found to be very effective and quite safe. Currently, two strains of the vaccine are in use: (1) the 17DD vaccine and (2) the 17D-204 vaccine. Both these vaccines protect against all known strains of the yellow fever virus.

**Dosage and administration** The vaccine is supplied freeze dried and must be stored at 2–8°C. It should be reconstituted just before use and given subcutaneously. It can be given together with other vaccines like Bacille Calmette-Guérin (BCG), polio, typhoid, hepatitis A and B and cholera. Live vaccines like measles and mumps and rubella (MMR) should be given on the same day, or separated by a month. Other flavivirus vaccines like *Japanese encephalitis* and *dengue* may interfere with the *yellow fever* vaccine, but there is insufficient data at present. World Health Organization (WHO) recommends this vaccine for all persons over 9 months of age who are living in or traveling to an endemic area. The contraindications and precautions to *yellow fever* vaccination are displayed in **Table 1**. The vaccine must be given at least 10 days before arrival in an endemic area.

**Efficacy** About 90% of vaccinees developed neutralizing antibodies in 10 days and almost 100% by day 21. Protective efficacy can be measured by the log neutralizing index or by plaque

reduction neutralization test (PRNT). Tests such as enzyme-linked immunosorbent assay (ELISA) and hyaluronic acid (HA) are nonspecific and not recommended.

**Duration of protection** Persistence of antibodies for 30–35 years has been shown. Protection is likely to be life long after one dose. However, international regulations require revaccination after a period of 10 years.

**Effectiveness** The vaccine is highly effective. After millions of doses administered, only five cases of yellow fever have been reported in vaccinated individuals. The vaccine has also been found to be effective in stopping epidemics.

**Vaccination during pregnancy and lactation** It is a live virus vaccine and therefore not recommended in pregnancy, although fetal anomalies have never been reported. Immune response to this vaccine is poor in pregnancy and revaccination is recommended after delivery if required for further travel. The vaccine is transmitted via breastmilk and neurological disease in babies has been reported. Nursing women should receive the vaccine after careful consideration.

**Vaccination of human immunodeficiency virus (HIV)-infected individuals** HIV-infected children can be given this vaccine if the CD4 counts are over 200/cmm and HIV ribonucleic acid (RNA) is less than 50 copies/mL. In these circumstances the vaccine is quite safe. However, the protection is poor and slow to develop and neutralizing antibodies should be measured 1 month after vaccination to detect nonresponders.

## ADVERSE EVENTS

Mild adverse events occur in 20–30% of recipients. These usually consist of low fever, headache, and myalgia and require only symptomatic treatment. Serious adverse events are of mainly three types: (1) hypersensitivity reactions, (2) neurotropic disease and (3) viscerotropic disease.

**Hypersensitivity reactions** The incidence is 8–18 people/million doses, and is most common in people with egg allergy, since the vaccine is prepared in embryonated eggs. Reactions can occur also to other components like gelatin, latex and chicken protein.

**Neurotropic disease** This was earlier called postvaccinal encephalitis. The current designation is yellow fever vaccine-associated neurotoxin disease (YEL-AND). Most of the reported cases were in babies under-9 months of age. The incidence of this adverse effect is estimated as 3–8/million vaccine doses. YEL-AND appears 4–24 days after the vaccine is given. It manifests as fever, headache and focal neurological signs. Other presentations are acute disseminated encephalomyelitis (ADEM) and the Guillain-Barré syndrome. On investigation, cerebrospinal fluid (CSF) pleocytosis, elevated CSF proteins, and elevated yellow fever virus specific immunoglobulin M (IgM) is found. The complication is often serious but rarely fatal. Although no specific treatment is available, most patients recover fully.

**Viscerotropic disease** This dangerous adverse effect, known as yellow fever vaccine-associated viscerotropic disease (YEL-AVD), was identified recently. The incidence is 3–4 persons/million vaccinated, and it is a serious, often fatal condition. YEL-AVD manifests with fever, jaundice, bleeding dyscrasias, and multiorgan failure. The manifestations start 2–5 days after the vaccine dose and can be moderate to severe. Hepatocellular enzymes are elevated and active viral replication and dissemination in multiple organs is seen. No specific treatment is available and only supportive treatment is recommended. Mortality is high. This complication is an important factor to consider when taking a decision about the yellow fever vaccine for a traveler.

**Table 1** Yellow fever vaccine—contraindications and precautions

Contraindications	Precautions
Allergy to the components	Age 6–9 months
Age less than 6 months	Pregnancy
Primary immunodeficiency	Lactation
HIV infection—symptomatic, or with CD4 counts less than 200/mm <sup>3</sup>	First time vaccination at age more than 60 years
Malignant neoplasm	Asymptomatic HIV infection and CD4 counts 200–499 mm <sup>3</sup>
Organ transplantation	Family history of yellow fever vaccine adverse effects
Immunosuppressive or immunomodulatory therapy	
Thymus disease	

Abbreviation: HIV, human immunodeficiency virus.

Source: Thomas RE, Lorenzetti DL, Spragins W, et al. The safety of yellow fever vaccine 17D or 17DD in children, pregnant women, HIV+ individuals, and older persons: systematic review. *Am J Trop Med Hyg*. 2012;86:359–72.

Severe complications of the yellow fever vaccine are most common at the extremes of age. Children below 6 months should not be vaccinated. Those between 6 months and 9 months should only be vaccinated if travel cannot be avoided and they have a high probability of infection.

### Vaccination for Travelers

Yellow fever is a serious and even fatal disease and no specific treatment is available. The vaccine is important for travelers to endemic areas, but it has serious adverse events. The risk of the disease should be balanced against the adverse effect profile of this vaccine for individual traveler and a decision to vaccinate (or not) should be taken after considering relevant factors (**Box 1**). Persons who cannot be given the vaccine should take other measures for avoiding this disease (**Box 2**).

#### BOX 1 Factors affecting decision to administer the yellow fever vaccine

- The specific destination. Risks for yellow fever are higher in Africa than in South America, and rural areas have a greater risk.
- The activities, recreational or work related, to be undertaken.
- The season of the year. Late monsoon and the period immediately after has high transmission.
- Local yellow fever transmission incidence and pattern.
- Likelihood of vector exposure.
- Risk factors for yellow fever vaccine-associated viscerotropic disease (YEL-AVD).

#### BOX 2 Other measures to avoid yellow fever

- Mosquito avoidance measures like full sleeved clothing and mosquito repellent cream in daytime.
- Sleeping under bed nets at night, though the yellow fever vectors are day biters.
- Spraying indoor spaces with insecticides.
- Staying in urban areas where disease transmission is low. Disease transmission is high in rural and forest areas.

### Legal Requirements

Many countries where yellow fever does not exist require travelers to produce a certificate of yellow fever vaccination. This is not for individual protection, but to prevent the import and establishment of the disease in the country.

### FUTURE VACCINES

For half a century the yellow fever vaccines were considered safe but the recent identification of YEL-AVD has caused concern.

This condition is rare but dangerous, and has led to a search for a safer vaccine. Also, the current live vaccines have a high incidence of neurological disease in infants and travelers of this age group cannot be protected.

An early effort to make a killed vaccine did not succeed but now a candidate vaccine named XRX-001 is under trial. It is a whole virus propionolactone preparation and has been found to induce neutralizing antibodies in recipients. This vaccine could be given to infants under-6 months of age, as well as during pregnancy and lactation.

Also under trial are vaccines in which the immunogenic component of the yellow fever virus has been inserted into other live vaccines that are safe. The yellow fever vaccine itself has been used as a base to make *Chimeric* vaccines against *dengue*, *West Nile fever* and *Japanese encephalitis*.

#### IN A NUTSHELL

1. Yellow fever is a serious and even fatal disease and no specific treatment is available.
2. It is caused by a virus of the family flaviviridae.
3. A safe and effective live-attenuated live vaccine, the 17D vaccine is available and in use for almost 80 years now.
4. Protection is likely to be life long after one dose. However, international regulations require revaccination after a period of 10 years.
5. Serious adverse events like hypersensitivity reactions, neurotropic disease and viscerotropic disease are rarely encountered.
6. It is recommended to use this vaccine for all persons over 9 months of age who are living in or traveling to an endemic area.

## Chapter 23.25

# Combination Vaccines

Niranjan Shendurnikar, Sheila Aiyer

The term combination vaccine implies a physical combination of two or more than two separate antigens/immunogens into a single preparation. This combination can be done at the time of its manufacture [diphtheria and tetanus toxoids and acellular pertussis with inactivated poliovirus, diphtheria and tetanus toxoids and whole-cell pertussis with hepatitis B, *Haemophilus influenzae* type b, measles, mumps and rubella (DTaP/IPV, DTwP/Hep B/Hib, MMR)] or is mixed and reconstituted into a single injection just before the vaccine administration (DTwP/Hib). The administration of any combination vaccine thus protects the recipient against more than one infectious disease. However, when a particular vaccine contains more than one antigen or a strain or a serotype of a single infectious organism it is not labeled as a combination vaccine. The classical example of such vaccines are Bacillus Calmette–Guérin (BCG) vaccine which contains different antigens of *Mycobacterium tuberculosis* and pneumococcal vaccines which contains different serotypes but are not labeled as combination vaccines. When two or more different vaccines are given to the recipient on the same visit but at different sites or routes, then these are termed as simultaneous vaccines [DTwP + oral polio vaccine (OPV) or inactivated polio vaccine (IPV)]. Vaccination providers should not combine separate vaccines into the same syringe to administer together unless mixing is explicitly specified. The presently available different combination vaccines and their preparations are shown in **Table 1**.

## BENEFITS OF COMBINATION VACCINES

The advent of pediatric combination vaccines offers several practical and logistic benefits both to the administration and the vaccine recipient.

- Combination vaccines reduce the number of injections and that infants and children receive during an immunization session, thereby reducing the pain in the vaccinee and the anxiety in the parents.
- It also reduces the amount of cumulative exposure to the preservatives and the stabilizers that may contribute the adverse events.

**Table 1** Combination vaccines currently available in India\*

<i>DTwP combinations</i>
• DTwP, DTwP/HB, DTwP/Hib, DTwP/Hib/HB and DT
<i>DTaP combinations</i>
• DTaP//Hib, DTaP/Hib/IPV, Tdap
<i>MMR (Measles, mumps and rubella)</i>
<i>Hepatitis A/Hepatitis B</i>

\*The names of vaccine before and after virgule (/) indicate that these vaccines are combined and supplied in the same vial or container; if there are two virgule(//) then these two vaccines are mixed or reconstituted just before the vaccine administration. A plus (+) indicates a separate but simultaneous administration.

**Abbreviations:** DTwP, diphtheria and tetanus toxoids and whole-cell pertussis; HB, hepatitis B; Hib, *Haemophilus influenzae* type b; DT, diphtheria and tetanus toxoids; DTaP, diphtheria and tetanus toxoids and acellular pertussis; IPV, inactivated poliovirus; MMR, measles, mumps and rubella.

- The lesser number of clinic visits, less costs and logistic requirements can ultimately increase the parental compliance and vaccine coverage.
- The administration of combination vaccines benefits the health establishment by reducing the storage space and handling and improving the cost effectiveness and the documentation process.
- The facilitation of uptake of a new vaccine when combined with an older vaccine. The availability of pentavalent combination vaccine has facilitated the incorporation of additional vaccine (Hib) into the national immunization schedule and thereby a higher immunization coverage. Advisory Committee on Immunization Practices (ACIP) recommends that licensed combination vaccines can be used whenever any components of the combination are indicated and its other components are not contraindicated. The use of combination vaccines generally is preferred over separate injections of the equivalent component vaccines.

## COMBINATION VACCINES AND IMMUNE RESPONSES

Although some earlier studies showed an altered immune responses to different vaccines when they were administered concurrently with other vaccines but at separate sites, there is no evidence that the efficacy of any vaccine recommended for routine use in childhood was materially altered by concomitant administration with any other vaccine(s) recommended for use at the same age. However, the techniques used to produce an antigen and/or a conjugation of a carrier proteins to a polysaccharide antigen vaccine (such as Hib or pneumococcal) can have important implications for the immunogenicity and the efficacy of the vaccine. The phenomenon of carrier induced specific suppression occurs when the antibody responses to the haptens on a carrier protein are inhibited by the prior immunization with the specific carrier. Thus the prior exposure to the carrier proteins, dose, route, choice of carrier protein and the adjuvants are the determinants of such a suppression or enhancement. Concurrent administration of two conjugate vaccines using same carrier proteins may lead to interference and unpredictable response and therefore simultaneous use of such vaccines must be evaluated for each vaccine combination and given only when recommended.

Chemical and physical interactions between the vaccine components and the adjuvants such as aluminum hydroxide by altering the binding and affect the immune responses to one or more vaccine antigens. Similarly presence of stabilizers, buffers and excipients may interfere with vaccine components of another vaccine. The immune response in viral combination vaccines is improved either by increasing the number of administered doses (OPV) or by modifying the concentrations of the individual virus strains (e.g., MMR vaccine or MMR-V vaccine).

## COMBINATIONS OF DTwP

Diphtheria and tetanus toxoids and whole-cell pertussis was the first combination vaccine licensed in 1948 and whole cell pertussis vaccine by itself is a potent adjuvant and the combination of three antigens (D, wP and T) enhances the immunogenicity of the toxoids when compared with their separate administration. The adsorption of aluminum to DTwP further improved the immunogenicity and reduced the severity of adverse reactions associated with pertussis component. DTwP-based combinations with other vaccines are one of the most widely used combination vaccines. Though many earlier studies showed that the combination of DTwP with Hib resulted

in reduced mean polyribosylribitol phosphate polysaccharide (PRP) antibody titer to Hib, as compared to when the components were given separately, the antibody levels were still high and in protective range and thus the reduced immunogenicity of Hib in combination with DTwP appears to be of no clinical significance. In general currently available combinations of DTwP with Hib and or Hep B do not result in clinically important interference amongst the different components without any increase in adverse reactions in frequency or severity when the same DTwP vaccine is given alone.

Addition of Hep B to DTwP has been reported to result in a higher anti-HBs antibodies and an unchanged DTwP response. Addition of Hib to this combination leads to no consistent changes in the antibody responses. Liquid DTwP/Hep B/Hib vaccine(s) are easily available and are widely integrated by several states in India in National Immunization Program. Studies have shown that the use of such vaccines either as liquid DTP/Hep B combination or mixing of DTwP liquid to the lyophilized Hib vaccine, these combinations have shown similar efficacy and side effects as when given separately. A study from India with a fully liquid DTwP/Hep B/Hib vaccine reported seroconversion rates of 99.4%, 99.4%, 89.9%, 97.8% and 98.3% respectively for D, T, P, Hep B and Hib components, respectively. The same brand of DTP vaccine and Hib vaccine as recommended by the manufacturer in combination must be used and not any DTP with any Hib vaccine. In western world combinations like DTwP + Hep B + IPV or even DTwP + Hep B + Hib + IPV are available as pentavalent or hexavalent vaccines and have shown similar efficacy and adverse reactions as when given separately.

### COMBINATIONS WITH ACELLULAR PERTUSSIS VACCINES (DTaP)

Combinations of DTaP with Hib conjugate vaccines showed a significantly reduced antibody response to Hib antigen. This resulted in a slowed development of DTaP/Hib combinations and lead to a development of alternate combinations such as DTaP/IPV, DTaP/Hep B and DTaP/IPV/Hep B vaccines. However in spite of a reduced response to Hib, most European nations do not regard this as clinically significant as this is unlikely to be clinically relevant after a few months of primary Hib immunizations. Additionally when the Hib vaccine is used in combination for the booster dose in infants who have been primed with the same vaccine in primary doses, then the immune responses are comparable to those when the Hib vaccine is coadministered as a separate dose. Experience in Indian studies has shown that Hib vaccine combined with DTaP or IPV and coadministered with Hep B has resulted in excellent responses to all the antigens including Hib-PRP.

The addition of Hep B with DTaP or with DTaP/IPV generally produces a somewhat higher response against DTaP and polio viruses than what are achieved with the same vaccines given separately on the same schedule. However, the lower Hep B antibody response observed in combinations than with separate Hep B vaccine are not due to antigenic interference but due to more closely spaced schedules for Hep B vaccination and particularly due to reduced interval between the second and third doses of Hep B vaccine (i.e., 6, 10 and 14 weeks or 2, 4 and 6 months instead of 0, 1 and 6 months). Several other childhood vaccines such as conjugate pneumococcal, meningococcal and rotavirus vaccines can be safely coadministered with DTaP and Hib containing vaccines.

### COMBINATION OF HEPATITIS A AND B VACCINE

Combination of Hep A and B vaccines is available in several countries including India in an adult formulation that contains

720 EU of Hep A antigen and 20 mcg of Hep B antigen. The vaccine has been immunogenic in a schedule of 0, 1 and 6 months. An accelerated schedule of 0, 7 and 21 days has been found to evoke an excellent immunogenic response and can be administered to individuals for who are at risk for both Hep A and B (such as certain/unprotected international travelers) for rapid protection against both Hep A and B infections. A two-dose schedule (0 and 6 months or 0 and 12 months) with an adult formulation has been found to be effective both for children and adults.

### COMBINATIONS OF MMR AND VARICELLA VACCINE

Measles, mumps, rubella and varicella (MMRV) vaccine was approved and became available in the United States of America in 2005 and clinical studies involving the healthy children between the ages of 1 month and 23 months indicated that those children who received a single dose of MMRV vaccine developed similar levels of antibodies to measles, mumps, rubella and varicella, as children who received MMR and varicella vaccines at separate injections sites. MMRV vaccine is approved for its use in the United States of America for children between the ages of 1 year and 12 years. The vaccine is not yet available in India. Other vaccines and which are presently available elsewhere but not licensed in India are listed in **Box 1**.

#### BOX 1 Other combination vaccines not licensed in India

- DTwP/Hib/IPV, DTwP/IPV, DT/IPV, Td/IPV
- DTaP/Hib/IPV/Hep B
- DTaP/Hib
- Hep B/Hib
- Hep A/Typhoid
- MMRV
- MnC/Hib

*Abbreviations:* DTwP, diphtheria and tetanus toxoids and whole-cell pertussis; Hib, *Haemophilus influenzae* type B; IPV, inactivated poliovirus; DT, diphtheria and tetanus toxoids; Td, tetanus and diphtheria; DTaP, diphtheria and tetanus toxoids and acellular pertussis; Hep B, hepatitis B; MMRV, measles, mumps, rubella and varicella.

### COMPLEXITIES OF COMBINATION VACCINES

Combination vaccines are preferred when a child qualifies for the components contained in the combination vaccine without any contraindication. Presence of an extra and approved component (antigen) in the vaccine is acceptable but not necessarily preferred. The safety of a new combination product is rigorously evaluated and compared against the safety of single antigen products or existing combination vaccines prior to authorization for use. There may be differences in minor adverse events associated with combination compared to single component vaccines, but they are not considered to be clinically significant. In case of an adverse event following immunization, determining which component of a combination vaccine is responsible may be more challenging than in single component vaccines.

With the refinement of vaccine development and production, children today are exposed to far fewer vaccine antigens than in the past, even though they are immunized against more infections with more combination vaccines. Advisory Committee on Immunization Practices (ACIP) recommends that combination vaccines be used whenever possible and as new vaccines that target previously unaddressed diseases are added to the vaccination calendar, the use and improvement of currently available combination vaccines will be paramount if high vaccine coverage is to be maintained.

### IN A NUTSHELL

1. Combination vaccine implies a physical combination of two or more than two separate antigens/immunogens into a single preparation.
2. Combination vaccines offer multiple benefits such as less number of painful injections, reduced hospital visits and logistic benefits such as improved administration and storage issues.
3. There is no evidence that the efficacy of any vaccine recommended for routine use in childhood is materially altered by concomitant administration with any other vaccine(s) recommended for use at the same age.
4. Combination vaccines are preferred when a child qualifies for the components contained in the combination vaccine without any contraindication.
5. Indian Academy of Pediatrics recommends that combination vaccines be used whenever possible and as new vaccines that target previously unaddressed diseases are added to the vaccination calendar.

## Chapter 23.26

# Immunization in Special Situations

Panna Choudhury

Every child has right to vaccination against vaccine preventable diseases. But, there are situations where immunizing some children become a challenging task due to various reasons which primarily include compromise in immunity status. Other situations like allergic disorders, bleeding diathesis, traveling to endemic areas also poses a problem and some of these will be discussed.

## IMMUNIZATION IN THE IMMUNOCOMPROMISED

While vaccinating an immunocompromised subject, the physician should judiciously weigh the expected benefits of immunization against the risk of adverse events. Generally, the vaccination in an immunocompromised is safer than often perceived. General principles for vaccination of the immunocompromised are:

- Inactivated vaccines are safer but immunogenicity and efficacy may be lower.
- All live vaccines are contraindicated in severe immunodeficiency (CD4+ count < 15%). In mild (CD4 count > 25%) and moderate (CD4 count 15–24%) immunodeficiency, live vaccines may be given if benefits outweigh the risks. Patients administered live vaccines inadvertently prior to diagnosis of immunodeficiency should be watched for vaccine related adverse effects.
- Antibody titers should preferably be checked postimmunization on regular basis and regular boosters may be administered if needed.
- More doses with higher potency should be given if indicated (e.g., Hepatitis B); antibody titers should be checked postimmunization/regular basis and regular boosters administered if needed. For major/contaminated wounds tetanus immunoglobulin (Ig) is required in addition to tetanus toxoid (TT) even if three or more doses of TT have been received in the past.
- Household contacts should not receive transmissible vaccines such as oral polio vaccine (OPV). Nontransmissible live vaccines such as measles, mumps and rubella (MMR) and varicella can be safely given. All household contacts should be fully immunized with varicella and influenza to reduce risk of transmission to the immunocompromised.
- If resources permits pneumococcal, varicella (depending on degree of immunocompromise and in two doses 4–12 weeks apart), hepatitis A, inactivated influenza vaccines should be given.
- At present data on safety and efficacy of the rotavirus and human papillomavirus (HPV) is insufficient.

## Congenital Immunodeficiency

In patients with severe B-cell immunodeficiency (X-linked agammaglobulinemia) live vaccines including OPV, Bacillus Calmette-Guérin (BCG), oral typhoid, and live-attenuated influenza are contraindicated. Measles and varicella vaccines may be given but may be ineffective due to concomitant Ig therapy. Inactivated vaccines may be given but are ineffective. In less severe B-cell deficiencies such as IgA and IgG subclass deficiency only OPV is contraindicated. In patients with severe T-cell immunodeficiency (SCID) all live vaccines are contraindicated and all vaccines are ineffective. Patients who have received live

vaccines especially BCG prior to diagnosis face an increased risk of complications including disseminated BCG disease. For patients with combined immunodeficiency such as DiGeorge syndrome, Wiskott Aldrich and ataxia telangiectasia, inactivated vaccines may be given but live vaccines are contraindicated. In complement deficiencies, all vaccines may be safely given; pneumococcal, *Haemophilus influenzae* type b (Hib) and meningococcal vaccines are particularly indicated. In patients with phagocyte defects such as chronic granulomatous disease, only live bacterial vaccines are contraindicated, other vaccines may be safely and effectively given.

## Human Immunodeficiency Virus Infection

Human immunodeficiency virus infection makes children prone to severe, recurrent or unusual infections by vaccine preventable pathogens. The efficacy and safety of vaccines depends on the degree of immunodeficiency. Generally, CD4+ counts less than 200 cells/cumm is known to elicit minimal or no host response. Antibody response also wanes at a faster rate in HIV-infected person. Antiretroviral therapy can improve immune responses to vaccine but not to the levels of an uninfected subject. Live viral and bacterial vaccines pose an enhanced risk for uncontrolled replication of the vaccine strains.

Vaccination is usually safe and effective early in infancy before HIV infection causes severe immune suppression. The duration of protection may be compromised as there is impairment of memory response with immunity wearing away. In older HIV1 infected children and adults, the immune response to primary immunization may be less but protective immunity to vaccines received prior to the infection is usually maintained. However immunity to measles, tetanus and hepatitis B wanes faster than other antigens.

World Health Organization (WHO) and Indian Academy of Pediatrics (IAP) recommend all the live vaccines in asymptomatic HIV1 infected children except BCG and OPV. However, in a symptomatic child live vaccines are not permissible, but at times measles/MMR/varicella vaccines may be considered on individual merit. Yellow fever vaccine is contraindicated in both symptomatic and asymptomatic. For killed vaccines in an HIV-infected child, ideally postvaccination regular monitoring of seroconversion are desirable. In an HIV-infected child, there is an enhanced risk of diseases like tuberculosis, hepatitis A, hepatitis B, measles, influenza, varicella, pneumococcal and meningococcal disease. In such situations physicians need to take a decision based on risk and benefit to the child. **Table 1** summarizes IAP recommendations for vaccination of HIV-infected children.

## Cancer Cases on Chemotherapy/Radiotherapy

Influence of cancer per se on immune function is minimal and does not contribute to a major extent in inducing immunocompromised state. However chemotherapy for cancer causes major secondary immunodeficiency. Radiotherapy does not affect the immune function to the extent of chemotherapy. Cancer cases need vaccination as they are prone to many vaccine preventable diseases as described here.

- Inactive influenza vaccine (IIV) should be given annually to all children aged older than or equal to 6 months with hematological malignancies or solid tumor malignancies except those receiving anti-B-cell antibodies or intensive chemotherapy, such as for induction or consolidation chemotherapy for acute leukemia.
- Pneumococcal conjugated vaccine (PCV) should be administered to newly diagnosed adults with hematological or solid malignancies and children with leukemia. Pneumococcal polysaccharide vaccine (23-valent) (PPSV23) should be administered to adults and children aged older than or equal to 2 years at least 8 weeks after PCV.

**Table 1** Immunization of HIV-infected children (IAP recommendations)

Vaccine	Asymptomatic	Symptomatic
BCG	Yes (at birth)	No
DTwP/DTaP/TT/Td/TdaP	Yes (as per routine schedule)	
Polio vaccines	<ul style="list-style-type: none"> <li>• IPV at 6, 10, 14 weeks, 15–18 months and 5 years</li> <li>• If indicated IPV to household contacts</li> <li>• If IPV is not affordable, OPV should be given</li> </ul>	
Measles	Yes, at 9 months	Yes, if CD4+ count > 15%
MMR	Yes, at 15 months and 5 years	Yes, if CD4+ count > 15%
Hepatitis B	Yes, at 0, 1 and 6 months	Yes, four doses, double dose, check for seroconversion, regular boosters
Hib	Yes (as per routine schedule)	
Pneumococcal vaccines (PCV and PPV23)	<ul style="list-style-type: none"> <li>• Yes (as per routine schedule)</li> <li>• What about PPV23 schedule?</li> <li>• One dose 2 months after PCV, second dose 5 years after first dose (not more than two doses)</li> </ul>	
Inactivated influenza vaccine	Yes (as per routine schedule)	
Rotavirus vaccine	Insufficient data to recommend	
Hepatitis A vaccine	Yes	Yes check for seroconversion, boosters if needed
Varicella vaccine	Yes, two doses at 4–12 weeks interval	<ul style="list-style-type: none"> <li>• Yes, if CD4 count ≥ 15%</li> <li>• Two doses at 4–12 weeks apart</li> </ul>
Vi typhoid vaccine	Yes (as per routine schedule)	
HPV vaccine	Yes (females only) as per routine schedule	

Abbreviations: BCG, Bacille Calmette-Guérin; DTwP, diphtheria and tetanus toxoids and whole-cell pertussis; DTaP, diphtheria and tetanus toxoids and acellular pertussis; TT, tetanus toxoid; Td, tetanus and diphtheria; TdaP, tetanus, diphtheria and acellular pertussis; IPV, inactivated poliovirus vaccine; OPV, oral polio vaccine; MMR, measles, mumps, rubella; Hib, *Haemophilus influenzae* type b; PCV, pneumococcal conjugated vaccine; PPV23, pneumococcal polysaccharide vaccine (23-valent); HPV, human papillomavirus.

- All inactivated vaccines can be considered for children who are receiving maintenance chemotherapy but these doses should not be considered valid unless there is documentation of a protective antibody level.
- Live viral vaccines should not be administered during chemotherapy.
- Three months after cancer chemotherapy, patients should be vaccinated with inactivated vaccines and the live vaccines for varicella, MMR as per schedule. In regimens that included anti-B-cell antibodies, vaccinations should be delayed at least 6 months.

### Corticosteroids/Other

#### Immunosuppressive Therapy

Children receiving high doses of oral corticosteroid (prednisolone > 2 mg/kg/day or for those weighing more than 10 kg, 20 mg/day or its equivalent for > 2 weeks) or immunosuppressive therapy should not receive live virus vaccines. Live vaccines can be given after the steroids have been discontinued for at least 1 month. Killed vaccines are safe but may be less efficacious. Children on inhaled, topical or low dose steroid therapy may be safely and effectively given their age appropriate vaccines. Physicians should always judge if immunization benefits outweigh risks.

#### Asplenia or Hyposplenia

Children with asplenia/hyposplenia are at high-risk of serious infections with encapsulated organisms. Asplenia or hyposplenia may result from sickle cell disease or radiation therapy involving spleen. Vaccination with pneumococcal (both conjugate and polysaccharide), Hib, meningococcal and typhoid vaccines is indicated in addition to all routine vaccines. All live vaccines may be safely given. In patients with planned splenectomy, vaccination should be initiated at least 2 weeks prior to splenectomy for

achieving a superior immunologic response. In those who have undergone emergency splenectomy, studies indicate that vaccination done 2 weeks after splenectomy is associated with a superior functional antibody response as compared to vaccination immediately following surgery.

### Chronic Diseases

Chronic neurologic, endocrinologic (diabetes), liver, renal, hematologic, cardiac, pulmonary and gastrointestinal disease cause increased risk of serious infections. These children should be offered pneumococcal, hepatitis A, varicella, influenza and rotavirus vaccines. The immunogenicity, efficacy and duration of protection of vaccines are lower than healthy children and hence if indicated higher antigen content/more doses (Hepatitis B), assessment for antibody response and frequent boosters (Hepatitis A and B) are recommended. It is important to stress the role of hepatitis A vaccine in patients with liver disease, pertussis boosting in those with stable neurologic disease. Children with severe cardiac and pulmonary diseases should receive pneumococcal and annual influenza vaccines. Live vaccines may be given safely in these children.

### IMMUNIZATION IN CHILDREN WITH HISTORY OF ALLERGY

Children should not receive a vaccine, if allergic to any of its components. The package label should be checked for vaccine constituents which in addition to antigen include stabilizers/buffers, preservatives, antibiotics and residue from the manufacturing process. Children with history of serious egg allergy should not receive *influenza* and *yellow fever* vaccines but can safely receive other vaccines including *measles* and MMR vaccines. Children with history of any hypersensitivity are at increased

risk for allergic reactions with inactivated *Japanese encephalitis* vaccines and thus should be monitored carefully. Children who had a serious hypersensitivity reaction to a particular vaccine must never receive it again. A mild reaction is not a contraindication to vaccination. In any case all children should be watched for at least 15 minutes after vaccination for allergy and resuscitation equipment should be kept standby.

## IMMUNIZATION IN RELATION TO ANTIBODY CONTAINING PRODUCTS

*(Whole blood, packed red cells, plasma and immunoglobulin)*

Inactivated vaccines can be safely administered simultaneously though at different site [exception administration of rabies immune globulin (RIG) 7 days after rabies vaccine]. Live vaccines including MMR and *varicella* should be avoided for at least 3 months after antibody containing products and antibody containing products should be avoided for 2 weeks after receipt of these vaccines. If immunization outside this prescribed period has occurred, serologic response should be checked and revaccination done if indicated. OPV and *yellow fever* may be given at any time in relation to antibody containing products. Rotavirus vaccine should be avoided for 6 weeks after giving antibody containing products but if this deferral results in vaccination being postponed beyond 15 weeks, the vaccine may be given.

## IMMUNIZATION DURING ILLNESS

Vaccination opportunity should not be missed during minor illnesses like upper respiratory tract infections, mild diarrhea and otitis media. However, in a moderate or severe acute illness vaccination may be postponed as immunogenicity may be lowered. Vaccination is also postponed as vaccine reaction may be mistakenly attributed to underlying illness.

## IMMUNIZATION OF CHILDREN WITH BLEEDING DISORDERS OR THOSE RECEIVING ANTICOAGULANTS

Hemophiliacs and children receiving anticoagulant therapy are at increased risk for bleeding after intramuscular injection. Vaccination can be scheduled shortly after administration of clotting factor replacement. A 23-gauge or smaller needle should be used for the vaccination and firm pressure without rubbing should be applied to the site for at least 5–10 min. Vaccines recommended for intramuscular injection could also be administered subcutaneously to in bleeding disorder cases if the immune response and clinical reaction to these vaccines are expected to be comparable by either route of injection, such as Hib conjugate vaccine, IPV, pneumococcal polysaccharide vaccine.

## IMMUNIZATION IN PREGNANCY AND LACTATION

Live vaccines are generally contraindicated in pregnant women. The yellow fever vaccine should be avoided in pregnant women as far as possible. However if travel is unavoidable, the vaccine should be given as the risks of infection outweigh the risks of vaccination (preferably in the first trimester). Measles, MMR and varicella vaccines are contraindicated in pregnancy and pregnancy should be avoided for 4 weeks after vaccination. If the vaccine is inadvertently given during pregnancy or pregnancy occurs within 4 weeks of vaccination, termination of pregnancy is not warranted. There have been no increased rates of congenital abnormalities in infants born to mothers inadvertently vaccinated in pregnancy. Measles, MMR and varicella vaccines can be safely given to contacts of pregnant women as these vaccines do not spread from vaccinee to contacts.

All inactivated vaccines may be safely given during pregnancy specially tetanus and diphtheria (Td)/tetanus toxoid (TT)/tetanus, diphtheria and acellular pertussis (Tdap) vaccines. IAP suggests immunization of pregnant women with a single dose of Tdap during the third trimester (preferred during 27 weeks through 36 weeks gestation) regardless of number of years from prior Td or Tdap vaccination. Tdap has to be repeated in every pregnancy irrespective of the status of previous immunization (with Tdap). Influenza and hepatitis B are other vaccines of importance in pregnant women. Rabies vaccine should be administered to pregnant women if indicated and is safe.

Passive immunization with Ig containing preparations is safe in pregnancy. All pregnant women should be evaluated for immunity to rubella, varicella and hepatitis B and those found susceptible should be vaccinated immediately after delivery. All pregnant women should be tested for HBsAg and if found HBsAg-positive should be followed carefully to ensure that the infant receives hepatitis B immune globulin (HBIG) and begins the hepatitis B vaccine series no later than 12 hours after birth and completes the recommended hepatitis B vaccine series on schedule.

All inactivated vaccines are safe in breastfeeding women and pose no harm to the babies. Live vaccines though may excrete poorly in breastmilk are also generally safe. Rubella vaccine may cause mild asymptomatic infection. The only exception to use of live vaccine during lactation is yellow fever vaccine as has been reported to cause infantile meningoencephalitis. If obligatory, then breastfeeding should be interrupted for the 10-day postvaccination viremic period.

## IMMUNIZATION IN PRETERM/ LOW BIRTHWEIGHT INFANTS

Generally, all vaccines may be administered as per schedule according to the chronological age. BCG and birth dose of OPV can be safely and effectively given to low birthweight (LBW) and preterm babies preferably at the time of discharge. The birth dose of hepatitis B vaccine can be administered at any time after birth in babies weighing more than 2 kg. However, in babies less than 2 kg immunogenicity of the birth dose may be low and as such preferably delayed till the age of 1 month. In babies less than 2 kg born to a hepatitis B positive mother, hepatitis B vaccine should be given along with HBIG within 12 hours of birth and three more doses at 1, 2 and 6 months are recommended. All other childhood vaccines may be given as per chronologic age and have acceptable safety, immunogenicity and efficacy. Full dose of the vaccines should be used. Since preterm and LBW babies may have low muscle mass, the use of needles with lengths of 5/8 inch or less is appropriate to ensure effective, safe and deep anterolateral thigh intramuscular administration.

## LAPSED IMMUNIZATION/PREPONED IMMUNIZATION/UNKNOWN IMMUNIZATION STATUS

Because of immune memory, there is no need to restart a vaccine sequence. Only the due doses should be given as in the original schedule irrespective of time lapse that has occurred. Doses should not be given 4 or less days from the minimum interval. In case of unknown immunization status, the child should be considered unimmunized and vaccinated accordingly. Minimum interval between the doses should be maintained and if for some reason given 5 or more days ahead of the minimum interval, the dose should not be counted. Serologic testing is also an option in patients with uncertain status but is usually not cost effective. It is better to vaccinate such children afresh to prevent missed opportunities.

## INTERCHANGEABILITY OF BRANDS

Brands of Hib, hepatitis B and hepatitis A may be safely interchanged with no compromise on immunogenicity and efficacy. However, vaccination with DTaP should be completed with the same brand as immunogenicity data different brands of DTaP is lacking. If previous brand is not known or not available any brand may be used.

## CATCH-UP IMMUNIZATION

In unimmunized or partially immunized older children any number of vaccines irrespective of live or inactivated may be given on the same day either singly or as combination vaccines maintaining a gap of 5 cm between vaccination sites (exception BCG and measles/MMR should not be given on the same day). Inactivated vaccines can be given at any time in relation to any other live/inactivated vaccines. If not given on the same day a gap of 4 weeks should be maintained between two live injectable vaccines especially MMR and *varicella* but also *yellow fever* and live-attenuated *influenza* vaccines. OPV, *rotavirus* and oral *typhoid* vaccines may be given at any time in relation to any live/inactivated vaccine. Vaccination schedule should be completed at the earliest for providing protection as early as possible.

## IN A NUTSHELL

1. Special situations needing considerations during immunization are immunocompromised conditions, allergic disorders, bleeding diathesis and traveling to endemic areas.
2. In immunocompromised children inactivated vaccines are safe. Live vaccines are contraindicated in severe immune deficiencies but may be given in moderate or mild deficiencies conditions if benefits outweigh risks. More doses or higher potency may be needed in certain situations. Household contacts of immunocompromised patients should not receive transmissible live vaccines such as OPV.
3. All live vaccines may be given in asymptomatic HIV-infected children except BCG and OPV. In symptomatic children live vaccines are contraindicated.
4. Chemotherapy for cancer causes major secondary immune deficiency and therefore, live viral vaccines should not be given to these cases; inactivated vaccines may be considered. Three months after cancer chemotherapy patients can be vaccinated with live and inactivated vaccines. Radiotherapy has less immune deficient effect.
5. Children receiving high doses of oral corticosteroid for more than 2 weeks or other immune suppressive therapy should not receive live virus vaccines. These vaccines can be given 1 month after the therapy has been discontinued.
6. Children with asplenia or hyposplenia should be given pneumococcal Hib, meningococcal and typhoid vaccines besides all routine vaccine.
7. In patients with chronic illnesses, higher antigen content or more doses of vaccines may be needed.
8. Patients who are allergic to any component of a vaccine should not receive that vaccine. Children with history of serious egg allergy should not receive influenza or yellow fever vaccine.
9. Live vaccines should be avoided for at least 3 months after blood transfusion or any antibody containing product administration except OPV and yellow fever vaccine.
10. Live vaccines are generally contraindicated in pregnant woman. All inactivated vaccines may be safely given during pregnancy. Passive immunization with IgG is safe. All vaccines are safe in breastfeeding women.

# PART VI The Adolescent

## Section 24 ADOLESCENT DEVELOPMENT

Section Editor MKC Nair

### Chapter 24.1

### Adolescence and Adolescent

MKC Nair, Paul Russell

WHO identifies adolescence as the period in human growth and development that occurs after childhood and before adulthood, from ages 10 to 19. It represents one of the critical transitions in the life span and is characterized by a tremendous pace in growth and change that is second only to that of infancy. Today, almost one in five persons in the world is an adolescent, that's 1.2 billion people between the ages 10 and 19 globally. The state of their health is important for their lives now and in the future, for this generation and the next. There are over 1.8 billion young people in the world today, 90% of whom live in developing countries, where they tend to make up a large proportion of the population. Adolescents account for over 20% of the population of India, amounting to over 250 million adolescents in the age group of 10–19 years.

#### ADOLESCENT RIGHTS

The adolescent being a child has the basic right as envisaged in the UN child rights declaration to (i) survival: right to life, health, nutrition, adequate standards of living; (ii) protection: freedom from exploitation, abuse, neglect, armed conflicts; (iii) development: right to education, leisure and recreation, development, social security and (iv) participation: freedom of expression, thought, conscience and religion. Out of the above, the one right that is most vital for comprehensive adolescent development is the right for participation. United Nations Children's Fund (UNICEF) has given a framework and outlines for the basic approach to promoting effective adolescent participation. The key points are: (i) start early, (ii) ensure that all adolescents are in a position to participate, (iii) build young people's capabilities to participate effectively, (iv) build adults' capacity to listen and to promote adolescent participation, (v) ensure that adolescents are well informed, (vi) believe in young people and allow them to be responsible, (vii) allow adolescents to take reasonable risks, (viii) make time for participation, (ix) make space for participation, (x) connect participation to young people's interest, (xi) be transparent, (xii) be honest, (xiii) don't patronize, (xiv) be democratic, (xv) create a supportive policy environment and (xvi) pay attention to bridging the gap between policy and practice.

#### CHARACTERISTICS OF ADOLESCENCE

Adolescence is the period following the onset of puberty during which a young person develops from a child into an adult. During

this rapidly changing developmental stage adolescents can shift moods quickly, vacillating between happiness and distress and self-confidence and worry. Some of these mood changes stem from biological sources. Increased hormones and changes to the brain structure arise from normal physical growth. Also, complex social interactions such as conflicts with friends, school pressures and experimentation with romantic relationships can exacerbate the labile emotional state of adolescents. It is also a time when adolescents begin to explore and assert their personal identities and when relationships with peers begin to take precedence over relationships with the family.

The rapidly changing social, political and economic scenario in the world has not left Indian family untouched. It is going through structural and functional modifications that have a bearing on adolescent's socialization and parent-child relations. Weakening of social support from kinship, movement of women empowerment, exposure to media, increasing competitive demands of the market economy and higher standards of achievement are a few aspects that have changed the family dynamics in the recent past. The need for differential values, competencies and coping styles between parents and adolescents are a source of anxiety and stress both for adolescents and parents. The ambiguity of values that adolescents observe in the adult world, the absence of powerful role models, increasing gaps between aspirations and possible achievements, not surprisingly, lead to alienation and identity diffusion. Parents themselves appear ill prepared to cope with social change, having grown up in hierarchically structured and interlinked social and caste groups that provided stability. The conflict between parents' desire to help their adolescent children cope with the changing demands of their own rootedness in tradition expresses itself in the *cold feet syndrome* when things go wrong. Parents who apparently seem modern, but if their child breaches established social codes, intergenerational conflicts related to marriage, career choice or separate living arrangements result in the tendency to fall back on tradition.

#### THEORIES OF ADOLESCENCE

According to the *biological theory* of adolescence by G Stanley Hall, Arnold Gesell and James Tanner, the focus of the period is physical and sexual development determined by genes and biology. The *psychological theory* (Sigmund Freud) focused on adolescence as a period of sexual excitement and anxiety. The main focus of *psychological theory of Erik Erikson* is on identity formation; adolescents struggle between achieving identity and identity diffusion. The *cognitive theory* of Jean Piaget emphasized on formal operational thought; moving beyond concrete, actual experiences and beginning to think in logical and abstract terms. In the *social cognitive theory* of Albert Bandura, the main focus is

on the relationship between learning social and environmental factors and their influence on behavior. The *cultural theory* of Margaret Mead emphasized on the influence of culture in which the adolescent grows up. Maslow's hierarchy of needs explains the need to progress through biological needs, safety needs, love and belonging needs, self-esteem needs, self-actualization needs to the ultimate, the transcendental needs.

## ADOLESCENTS' NEEDS AND PROBLEMS

An individual's needs and problems influence his development to a great extent. Adolescence is a crucial period in the life of an individual with its characteristic needs and problems of adjustment. Every adolescent has certain needs, the satisfaction of which is essential to his continued physical and other aspects of development. A need is a tension within an organism which must be satisfied for the well-being of the organism. When a need is satisfied, the tension is released and the individual experiences satisfaction.

There are certain basic needs which are functioning in every individual. They are broadly classified into *physiological needs* and *psychological needs*. The fulfillment of physiological needs is inevitable because they are concerned with the very existence of the individual. The need for oxygen, need for water and food, need for rest and sleep, need for sex gratification etc. are the important physiological needs. Needs that are associated with sociocultural environment of an individual are called *secondary needs*. They are acquired through social learning and their satisfaction is necessary for the psychological well-being of the individual. The important sociopsychological needs are as follows: (i) need for security, (ii) need for love, (iii) need for approval, (iv) need for freedom and independence and (v) need for self-expression and achievement.

### Problems of Adolescents in the Indian Context

Any period of development is likely to be accompanied by many potential difficulties. Adolescence is a period of transition from childhood to adulthood that implies many development changes and associated problems. Some of the outstanding problems of Indian adolescence are the following:

#### *Perplexity with Regard to Somatic Variation*

Every adolescent has more or less difficult task of adjusting to somatic variation which may occur in connection with puberty. The flow of blood during menstruation in girls and nocturnal emission in boys creates worries and gives birth to so many fears and anxieties.

#### *Problems Related with Intensification of Sex Consciousness*

The sudden awakening of sex instinct during adolescence results in intensification of sex consciousness. Adolescents are curious to know about sex related topics and are seeking answers to their innumerable doubts in sexual matters. In our country, some of the parents are illiterate and they do not have scientific knowledge of sexual matters.

#### *Adjustment Difficulties with Parents*

Adolescents have a strong desire for freedom and independence. The conflict between parental norms of behavior and peer group relationships often leads to friction in the relationship and adolescents find it difficult to adjust to the needs and demands of parents. Failure to adjust with the parents may result in revolting against parents and authority.

### *Childhood-adulthood Conflict*

In our society, the adolescent is considered neither as a child nor as an adult. He/she has to depend on his parents and elders for his physical and emotional needs. But at the same time, he wants to hold independent views and opinions like an adult. He/she can very well manage his own affairs and resist any unnecessary interference from elders. He/she begins to feel ashamed and embarrassed for the protection and care shown by the parents.

#### *Adjustment Difficulties with School Discipline*

Most of the adolescents face a great problem in adjusting with school discipline. Sometimes school expects too much from students who must submit to teachers who may be tyrannical sometimes.

#### *Adjustment Difficulties with Community*

The adolescent is expected to find his place in a society marked by increasing social isolation and rapid technological changes. This changing world makes it difficult to anticipate and plan for adolescent life.

## COMMUNITY ADOLESCENT CARE COUNSELING PROGRAMS

A healthy adolescent is the product of a series of steps including caring for the pregnant woman, prevention of low birth weight babies, caring for the young child between 0 and 6 years, compulsory primary education for both boys and girls and care of the vulnerable adolescent period. Adolescence is a period of experimenting, experiencing and expanding, and needs parental and societal support to safeguard, protect and guide him/her safely through this rebellious period. Adolescents need help and guidance in decision making, problem solving, critical thinking, developing interpersonal skills, self-awareness, empathy, coping with stress and managing emotions.

India has a sizeable adolescent population and they constitute a vulnerable group for both mental and physical illnesses, and yet their health-care needs and delivery systems are neither well defined nor developed. Conventional health service systems did not, until very recently in India, consider adolescent health as a vital aspect of health service development in the country. The importance of adolescent health, especially enhancing the mental health as well as sexual and reproductive health has been documented. The research on child and adolescent mental health is only 3-6% of all published mental health research in the world and research base from India in this vulnerable population is negligible. Similarly, although service and delivery models have been enhanced for the Adolescent Reproductive and Sexual Health (ARSH) in India, the evidence base about the needs and interventions aimed at individual to community level is still evolving like: (i) community adolescent health care and education model, (ii) school-based family life education and counseling model, (iii) school-based adolescent care services, district model.

Many of the mental, reproductive and nutritional health needs of the adolescent population are required to be addressed and can be addressed in the primary care pediatric setting itself, if the current system of health-care can be reorganized. This restructuring will be more effective for this population if adolescent friendly approaches, public-private partnership and policy as well as sectoral linkage between the National Rural Health Mission (NRHM) and other national programs are achieved. The health program for this age group should have promotive and preventive as well as remedial and curative components. Also, improving the availability of trained personnel in these areas of health, culturally

sensitive evidence-based approaches and capacity building in the primary care approach is essential to ensure the viability of adolescent health-care in this country.

Currently, at the national level, there are efforts to develop and bring adolescent health services as part of the child health-care in India under Reproductive, Maternal, Newborn, Child and Adolescent Health (RMNCH+A) and Rashtriya Bal Swasthya Karyakram (RBSK). What we need to appreciate is that a direct approach on sexuality issues is not acceptable to Indian parents and many adolescents themselves. Hence, we need to choose a more appropriate stepwise approach of family life and life skill education, counseling for scholastic issues and reproductive issues like menstrual problems, reproductive tract infections and polycystic ovary syndrome and reserve sexuality issues for those who have completed 18 years of age.

## ADOLESCENT OFFICE PRACTICE

We need more and more general practitioners getting interested in adolescent pediatrics as a subspecialty for overall improvement in providing adolescent care and counseling. Adolescent office practice should have the following components:

### Routine Medical Care

The medical problems identified among adolescents namely, headache, refractory error, urinary tract infection, dandruff, acne, allergic rhinitis, dysmenorrhea and leukorrhea, anemia, iodine deficiency, undernutrition, overweight and obesity, body image problems, lifestyle diseases, polycystic ovarian syndrome (PCOS), acne and other cosmetology issues, dandruff and seborrhea, dental caries and problems, genitourinary infections, sexually transmitted infections, sexual abuse or empowerment issues, teenage pregnancy or contraceptives, pelvic inflammatory disease, drug therapy and individual counseling for mental health issues are problems that can be tackled by a trained adolescent pediatrician.

### Adolescent Immunization

As per Indian Academy of Pediatrics (IAP) Immunization Schedule.

### Family Life Education

Family life education should include the following topics: (i) growth, nutrition, maturation and body image, (ii) reproductive health, (iii) life skills development, (iv) improving study habits, (v) avoiding substance abuse and HIV/AIDS, (vi) adolescent mental health problems and counseling.

### Nutrition, Body Image and Prevention of Obesity

Because adolescents experience significant physical changes in their bodies during puberty, they are likely to experience highly dynamic perceptions of body image. Body image is influenced strongly by self-esteem and self-evaluation, more so than by external evaluation by others. It can, however, be powerfully influenced and affected by cultural messages and societal standards of appearance and attractiveness. In the western world, 85% of young women worry *a lot* about how they look, however, and twice as many males as females say they are satisfied with their appearance.

### Screening for Lifestyle Diseases

The rising burden of preventable risk factors for noncommunicable diseases (NCDs) among adolescents is a major public health challenge worldwide. NCDs like obesity, diabetes mellitus, hypertension, coronary artery disease, stroke in adults have been related to the prevalence of risk factors in childhood. Singh et al, documented inappropriate dietary practices (fast food consumption, low fruit consumption), low physical activity,

higher level of experimentation with alcohol and to a lesser extent smoking, high prevalence of obesity and hypertension in the school children. Khuwaja et al, reported that over 80% of the adolescents in Pakistan had unhealthy diets and 54% were physically inactive. Most adolescents were exposed to passive smoking, and 14% were also current smokers.

The *fetal origins hypothesis* proposes that NCDs including coronary heart disease, type 2 diabetes and hypertension originate through the responses of a fetus to under nutrition that permanently change the structure and function of the body. Child Development Centre (CDC) Kerala follow-up study observed that high triglyceride values and overweight/obesity were significantly more in low birth weight adolescents when compared to normal birth weight adolescents. These results may have policy implications in planning adolescent nutrition and care programs in India.

Adolescents need further evaluation if BP is more than 130/80 mm Hg. These children should also be screened for hypercholesterolemia. Indications for drug therapy (cholestyramine/niacin/statins) in those above 10 years include: (i) low density lipoprotein (LDL)  $\geq 190$  after 6–12 months of diet therapy; (ii) LDL  $\geq 160$  and family history of early coronary vessel disease; or (iii) LDL  $\geq 160$  and 2 or more risk factors like; obesity, smoking, hypertension, diabetes and inactivity.

### Screening for Reproductive Health Disorders

Health-care providers can provide important information on sexuality and reproductive health, and need to be able to communicate this information without restriction to patients in private. This includes the provision of sexuality information and healthcare to minors without parental consent or notification. Comprehensive school-based family life education that is appropriate to students' age and developmental level is an essential part of education programs for every age.

### Preventing STIs, HIV and Teenage Pregnancy

In India, although traditional norms oppose premarital sex, some studies indicate a growing trend toward premarital sexual activities among adolescents. An intervention study conducted among Lucknow slum boys has shown that approximately 15–17% of youths reported intercourse outside of marriage, including about 3% who reported intercourse with a prostitute and 3% who reported oral or anal sex with another male. After the intervention, awareness that STIs including HIV/AIDS could be acquired from women other than prostitutes increased significantly from 50% to 76% in the intervention group. However, young men's awareness that they were personally at risk of acquiring STIs changed little during the intervention.

Unmarried pregnancy is not acceptable at all to the Indian parents and there is huge social stigma attached to it. A case control study conducted in Kerala regarding risk factors for pregnancy among unmarried adolescents and young adults has shown a strong association between unmarried adolescent pregnancy and lack of parental supervision [odds ratio (OR) 8.74], poor intra-family relationship (OR 7.01), lack of knowledge on sexual and reproductive health (OR 4.95), family problem (OR 4.41) and non-engagement of adolescent in any productive activity (OR 4.41).

### Adolescent Reproductive Tract Infections among Girls

Among 427 unmarried girls seen in community adolescent clinic settings in Kerala, the mean age at menarche of the participants was 12.3 years. On clinical examination by lady gynecologist, 20.1% had vulvitis and more than 50% had mild to moderate discharge, 42.4% being normal mucoid discharge and 10.3% yellow or thick curdy discharge. On laboratory examination, 5.6% had KOH

mount positive, suggestive of candidiasis and 7% suggestive of bacterial vaginosis. More than one-third of the school going girls does not use school toilets. For majority of girls with external genital itching, apart from good menstrual hygiene, washing and drying properly the local area before going to sleep, use of local antifungal ointment or powder is adequate. However, for more serious infections with curdy white discharge and intense vulvar itching, the drug of choice is fluconazole 150 mg as a single dose which may be repeated after 1 week.

### Adolescent Counseling

Aim of adolescent counseling would be maintaining the client's adaptive patterns, modifying maladaptive patterns and enhancing motivation of the client. The counseling steps would include: (i) rapport building with the adolescent, (ii) ventilation or catharsis of adolescent's problems, (iii) prioritizing problems, (iv) understanding the context and self-role in creating the problem, (v) choices of solutions from adolescent's perspective, (vi) helping to choose and implementing the right choice, (vii) termination of the professional relationship between adolescent and the pediatrician. Counseling is further detailed in Chapter 26.2.

### Screening for Mental Health Disorders

Adolescent mental health issues have to be addressed by the general practitioners/pediatrician/physician because there are far too many adolescents with behavioral and emotional problems in the community and only limited number of psychiatrists and trained clinical psychologists available. We have to recognize early signs of psychosocial problems for better results and the pediatrician, who have been seeing the child and who knows the family well for a long time, would be the ideal person to do so. Both parents and children have to be made comfortable in a nonstigmatizing service delivery system. Many of the adult psychiatric disorders have their onset in adolescence. Half of lifetime diagnosable mental health disorders start by age 14; this number increases to three-fourths by age 24. The evidence shows that one in five adolescents experiences significant symptoms of emotional distress and nearly one in ten is emotionally impaired and the most common disorders among adolescents include depression, anxiety disorders and attention deficit hyperactivity disorder and substance use disorder.

Mental health in adolescents is dealt with in detail in Chapter 25.3.

### Premarital Counseling Services

Although ideally premarital counseling should be given to persons above 18 years, but in the Indian context, because of high prevalence of early marriages premarital counseling could be offered to any young adult over 15 years of age. The counseling sessions should include: (i) family life and life skill education, (ii) enhancing coping strategies, (iii) improving communication strategies, (iv) guidance on morality or spirituality issues, (v) self-empowerment both economic and social, (vi) prevention of intrauterine infections like rubella, hepatitis B, human papilloma virus vaccinations, (vii) screening for STIs or HIV,

lifestyle disease markers, mental health and reproductive health, (viii) medical examination including breast and external genitalia, (ix) transabdominal ultrasound examination if indicated and (x) sex and sexuality skills needed in family life including understanding needs of self as well as the partner. While examining any adolescent and particularly a female adolescent, it is a must (i) to have presence of her mother, (ii) explain what specific examination you are going to do and why and (iii) get her permission at every stage of examination in a reassuring way.

### IN A NUTSHELL

1. WHO identifies adolescence as the period in human growth and development that occurs after childhood and before adulthood, from ages 10 to 19.
2. Adolescence is a crucial period in the life of an individual with its characteristic needs and problems of adjustment.
3. The important sociopsychological needs of adolescents are: (i) need for security, (ii) need for love, (iii) need for approval, (iv) need for freedom and independence and (v) need for self-expression and achievement.
4. India has a sizeable adolescent population and they constitute a vulnerable group for both mental and physical illnesses, and yet their health-care needs and delivery systems are neither well defined nor developed.
5. Pediatricians need to incorporate care of the adolescents in their office practice including health-care, life skill education, and counseling.

## Chapter 24.2

# Sexual Development and Sexuality

Chandrika Rao

The development of reproductive organs is determined by the presence and action of sex chromosomes, sex-determining genes and a number of hormones in a coordinated manner starting early in fetal life. The development and differentiation of both internal and external genitalia are now believed to be active processes guided by genes and hormones in the presence of gonads (see Chapter 44.20 for details). Any discordance in the development may lead to disorders of sexual development (DSD).

### PUBERTY AND SEXUAL MATURITY RATING

Puberty is the phase of transition from the sexually immature child to the mature, potentially fertile adolescent and adult. The physiology of normal pubertal development in boys and girls, its regulation by the hypothalamic-pituitary-gonadal (HPG) axis as well as the physical changes associated with puberty in both genders are detailed in Chapter 44.10. The standard clinical system for describing normal pubertal development, which includes the somatic and physiologic changes in the external genitalia and breasts, is the five-stage system of sexual maturity rating (SMR) system described by Tanner and Marshall (see Chapter 44.10 for details).

### Implications of Pubertal Assessment for the Pediatrician

Assessment of puberty by SMR helps in the diagnosis of not only disorders of puberty and DSD, but also in disorders of growth and development and many systemic and genetic disorders. It should be done patiently after establishment of rapport between the adolescent and the pediatrician. Adolescents, who are uncomfortable of the examination of private areas of their body, can indicate development in a Tanner chart which can be confirmed later.

Minor asymmetry of breasts is a common normal variant in adolescent girls. The most common breast abnormality noted in adolescent girls is a mass, mostly due to a benign cyst or fibroadenoma. Tenderness with swelling of breasts especially in a cyclic pattern may occur during the premenstrual period in some girls. They need appropriate counseling to alleviate their apprehensions.

Testicular size is the earliest reliable sign of puberty and an important part of examination of boys. Testicular size is assessed by Prader orchidometer (**Fig. 1**). The beads correspond to testicular volumes of 1 mL through 25 mL. Other methods of measurement of testes include rulers, calipers and ultrasound. Ultrasound is probably the most accurate measurement method. The clinician should check for whether the testes are descended and there is hypospadias. Prepubertal boys nearly always have a testicular length of 2.5 cm or less, or volume of 4 mL or less. As puberty progresses, the increase in testicular size usually precede the increase in penis size and eventually reaches the adult size of 5.0 cm or 25 mL. To measure penile length accurately, use either a ruler pressed at the base of the penis while applying firm stretch to the penis itself. In normal prepubertal boys, the penile length ranges from 5–7 cm.

**Figure 1** Prader orchidometer

### GYNECOMASTIA

Gynecomastia is a benign enlargement of male breast. This may be unilateral or bilateral. Histologically, it contains glandular tissue proliferation of mammary tissue. In true gynecomastia, the breast enlargement is due to glandular breast tissue and in pseudogynecomastia, excess adipose tissue is the cause of the enlarged chest. It is marked by the diffuse fatty tissue infiltration of the breast and axillary areas. A detailed discussion on gynecomastia is given in Chapter 44.13.

### MENSTRUATION

The average age at menarche (the first menstrual period) has shown a secular trend in most affluent countries. In urban Indian girls it occurs at around 12.6 years, whereas for rural Indian girls it is still around 15–16 years.

The menstrual cycle usually lasts for 28–35 days, beginning from the first day of bleeding to the first day of the next cycle. The bleeding may last for 3–5 days with 50–200 mL blood loss in each cycle. The ovarian cycle consists of three phases of a *follicular phase* followed by *ovulation* and later a *luteal phase*. The uterine cycle is divided into menstruation followed by a *proliferative phase* and a *secretory phase*. The rhythm of these cycles depends on the intact hypothalamic-pituitary-ovarian (HPO) axis.

At puberty, the hypothalamus secretes gonadotropin-releasing hormone (GnRH) in a pulsatile manner which activates the HPO axis with secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Anterior pituitary releases FSH which stimulates ovarian primordial follicles into Graafian follicles. In each cycle, one Graafian follicle dominates, matures and ovulates. The Graafian follicle secretes 17 $\beta$ -estradiol which causes endometrial proliferation. During the follicular phase, estradiol suppresses the secretion of LH. As the ovum matures, the levels of estradiol reach a threshold where it stimulates secretion of LH (*LH surge*) and inhibin secretion and inhibits secretion of FSH. Estrogen secretion peaks 48 hours before ovulation and LH secretion peaks 24–36 hours before ovulation.

At ovulation, follicle ruptures and forms corpus luteum. The theca cells in ovary produce testosterone and androstenedione. Progesterone secreted by corpus luteum stimulates endometrium to undergo secretory hypertrophy and inhibits LH secretion. If fertilization is absent in that cycle, estrogen and progesterone levels gradually decline and endometrial lining is shed which causes menstruation. In an anovulatory cycle, a thin necrotic

superficial layer of endometrium is shed with vascular changes and secretion of prostaglandin E2 (PGE2). This causes myometrial contraction and vasodilatation. Prostaglandin F2- $\alpha$  (PGF2 $\alpha$ ) causes vasoconstriction. PGE2 and PGF2 $\alpha$  are responsible for dysmenorrhea while prostaglandin I2 (PGI2) causes muscle relaxation and vasodilatation and abnormal secretion can cause menorrhagia.

In about 50% of the girls, the initial cycles and those up to 2 years may be anovulatory and irregular, prolonged, scanty or excessive.

### Implications for a Pediatrician in Menstrual Disorders

Menstrual irregularities are common among school girls of 15–17 years—around 20% self-report menstrual irregularities whereas about 13% have confirmed menstrual irregularity as per the standard criteria used by a gynecologist. The most common menstrual problems reported among the school girls were dysmenorrhea (72%) followed by back pain (40%), fatigue (36%), pain over the arms and legs (28%), loss of appetite (18%), headache (14%) and vomiting (6%). The roles of the pediatrician in adolescent girl seeking counseling are as follows:

- Encourage the girl and mother to discuss menarche and menstrual cycles, and problems if any, during routine clinical contacts.
- Individual problems like irregular menstrual cycles or dysmenorrhea need to be diagnosed, counseled and treated early.
- Menstrual hygiene should be discussed.
- Need for proper diet and exercise should be stressed.
- Advice regarding hematinic and treatment of anemia—weekly dose of 100 mg of elemental iron with 500  $\mu$ g of folic acid and biannual deworming.

## DEVELOPMENT OF SEXUALITY AND GENDER IDENTITY

Sexuality deals with sexual behavior, sexual orientation, sexual interest and fantasies, attitudes toward sex and the awareness of socially defined and accepted sexual roles, values and traditions. Some of the important terms and definitions used while discussing sexuality and gender identity are described below:

### Anatomic Sex

It refers to the anatomic appearance of the sexual reproductive organs. Anatomic sex is only one component of sexuality.

### Gender Identity

It refers to the inside feeling of oneself as either masculine or feminine. Gender identity and anatomic sex sometimes do not match. For example, a person can be born as a boy but feel like a girl. This is sometimes referred to as transgender. Transgender individuals and transvestites may not have matching gender identity to the biological sex. Transgender individuals and transvestites can be heterosexual, homosexual or bisexual.

### Gender Role

It is the outward expression of maleness or femaleness. It is the public image of being male or female that a person presents to others.

### Sexual Orientation

It refers to the sexual attraction one feels toward another person. It refers to an individual's pattern of physical and emotional arousal toward other persons. Heterosexual individuals are attracted to persons of the opposite sex, homosexual individuals (often referred

to as *gay* and *lesbian*) are attracted to persons of the same gender and bisexual individuals are attracted to persons of both genders. Sexual orientation is not synonymous with sexual activity or sexual behavior. Sexual orientation is influenced by many factors including anatomic sex, gender identity and the society.

### Asexuality

It refers to having no sexual attraction to a person of either gender.

It is common for adolescents to feel confused about their sexual orientation, which is normal. These feelings may change as person matures or may persist. It is important for adolescents and adults to be comfortable with all aspects of sexuality (anatomic sex, gender identity and sexual orientation).

Adolescents may date casually without commitment. They begin as mixed-gender group friendships in preadolescence. Peer pressure, communication skills, body image issues and self-esteem play a major role here. As they grow older, group dating and later dyadic (or couple) dating with increasing levels of intimacy and commitment develop and may result in cohabitation and/or marriage. Friendship networks often play important and varied roles in the dating process. The various changes that occur in sexuality during the adolescence are listed in **Table 1**.

## Development of Sexuality

Various theories have been formulated on the development of human sexuality. They are discussed in brief below:

### Freud's Theory

According to Freud and psychoanalytic theory, the stages of psychosexual development are genetically determined. Freud believed that adolescent sexuality was influenced by behavioral, social and emotional changes and the influences on the self-

**Table 1** Sexuality in early, mid and late adolescence

Early adolescence	Middle adolescence	Late adolescence
<ul style="list-style-type: none"> <li>• Girls bolder than boys</li> <li>• Same-sex friends and group activities</li> <li>• Shyness, blushing and modesty</li> <li>• Greater interest in privacy</li> <li>• Experimentation with body—masturbation, associated with guilt</li> <li>• Worries about being normal—gay, lesbian and bisexual youth may feel differently without knowing why</li> <li>• Sexual fantasies common</li> <li>• Sexual activities are usually nonphysical</li> <li>• Early adolescents are often highly content with non-sexual interactions such as telephone calls to peers</li> </ul>	<ul style="list-style-type: none"> <li>• Concerns about sexual attractiveness</li> <li>• Frequently changing relationships</li> <li>• Movement toward heterosexuality with fears of homosexuality</li> <li>• Tenderness and fears shown toward opposite gender</li> <li>• Feelings of love and passion</li> <li>• Noncoital and coital contacts are prevalent</li> <li>• Sexual behaviors do not always match sexual identity</li> <li>• Denial of consequences of sexual behavior is typical—improving with age</li> </ul>	<ul style="list-style-type: none"> <li>• Concerned with serious relationships</li> <li>• Clear sexual identity</li> <li>• Capacities for tender and sensual love</li> </ul>

image. He also stated that the physiological changes are related to increase in negative emotions such as anxiety, tension and other forms of adolescent behavior.

### Anna Freud's Theory

She assigned greater importance to the relationship between the id, the ego and the superego. She believed adolescent conflicts depend on the strength and coping ability of id and ego of the individual.

### Erikson's Theory

He described adolescence as the period during which sense of personal identity is established and is more important than sexuality. He believed that this must be acquired through individual efforts; contact with peers and one's values all contributing to a stable identity. This influences the adolescent in adulthood. If the adolescent adopts someone else's identity or ideology, it rarely becomes satisfactory and can lead to self-doubt, role confusion and the adolescent may indulge in self-destructive activity in adolescence.

### Social Learning Theory

#### (Modeling, Imitation and Identification)

Usually, children imitate parents and later the teacher. During adolescence the peer group and selected social models like actors may form role models.

### Other Theories

Two theorists, Bandura and Hollingworth, believed that human development is a continuous process and social conditions are responsible for naming adolescence as a *transition stage* and it is not some intrinsic aspect of human development.

### Mead's Theory

It states that *in most societies adolescence is a period of reorientation*. The normal milestones of sexual play and activities are described in **Table 2**.

## ADOLESCENT HOMOSEXUALITY

Pediatricians dealing with adolescent ages may often have questions on sexual behavior and sexual orientation addressed to them. Adolescents may have doubts about sexual orientation and

may seek information from physicians about illnesses, sexually transmitted diseases or substance abuse. Health issues concerning sexual behavior are varied and are different from normal disease spectrum that pediatricians are used to. Hence, it is necessary for pediatricians to be comfortable in dealing with normal adolescents with curious questions and adolescents who go through different experiences. The pediatrician should be alert to depression, anxiety, low self-esteem and aggression. Sexual history should be done in a gender-neutral manner. It is better to phrase the question as—“*Is there anyone you are romantically interested in? Have you ever had sex with anyone?*” Counseling is necessary along with a thorough medical history, physical examination, appropriate immunizations [e.g. human papillomavirus (HPV) and hepatitis A and B], selective laboratory tests [e.g. human immunodeficiency virus (HIV), hepatitis A, B and C, sexually transmitted infections] and appropriate treatment as necessary.

## Implications for the Pediatrician Dealing with Sexuality Issues

- Assure confidentiality. Personal interview is necessary. Parents may have concerns which they are reluctant to discuss with their children and separate interviews may be desirable at time to maintain confidentiality.
- Pediatrician should keep in mind that physical maturation may correlate with sexual maturity whereas psychosocial development correlates more closely with chronologic age.
- Questions in history should be gender neutral.
- Nonjudgmental language should be used. Questions like “*Who is your boyfriend or girlfriend?*” can be better worded as “*Are you interested in anyone romantically?*”
- Information on gender, sexual orientation and resource groups in the clinic or hospital will encourage adolescents to ask questions.
- History should include questions on risk behaviors, depression and suicidal thoughts.
- The pediatrician should provide *safe sex* guidelines and information on protection to adolescents who are sexually active.
- It is ideal to counsel all adolescents about substance use (alcohol, marijuana and other drugs) and unsafe sexual intercourse.
- It may be necessary to perform investigations such as tests for sexually transmitted diseases, HIV or pregnancy depending on the clinical information.
- If adolescent has homosexual activity, urethral (or urine), pharyngeal and anal swabs for gonorrhea, urethral culture or urine for chlamydia, anal cytology and stool culture testing, ova and parasite should be done.
- Immunization to prevent cervical cancer (HPV vaccine) and hepatitis A, B should be offered.
- Information on sexual abuse and violence should be offered.
- Pediatrician and the resource personnel should not have personal bias in providing care to adolescents who have expressed their sexual orientation to the health-care providers. If nonjudgmental environment cannot be assured, adolescent should be referred to a better equipped center.

## NOCTURNAL EMISSION

Nocturnal emission is emission of semen in men or lubrication of vagina in women at night in sleep. It is common in teens and young adults. The person can sleep through it or wake up during the event. Frequency is variable and may vary to multiple episodes per month in teens to 1–2 per month in men. Multiple episodes with dizziness, weakness and insomnia are considered pathological. Local causes of abnormal emissions

**Table 2** Normal milestones of sexual play

Age group	Sexual play and activities
0–3 years	Children are egocentric
3–4 years	Boys and girls may hug, kiss and may have future plans which may not be understood by them
4 years	Awareness of differences in male and female genitalia and awareness when micturating. Play involves house play with gender roles and doctor games
5–11 years	Self-consciousness sets in. Hugging, kissing and showing may continue but decrease. Boys and girls may hate each other. Teasing occurs
Preadolescence	Jokes and secrets about sexual activities, display knowledge of sexual words, talk about sex with same sex friends
Adolescence	Exchange letters, dance, attend parties with mixed genders, kiss, have a steady partner, activities like fondling, oral-genital contact and intercourse may occur

are inflammatory diseases of the posterior urethra (urethritis), prostate (prostatitis), seminal vesicles and vas deferens (vasitis). Continued existence of inflammation in the genitals leads to constant irritation of nerve endings and the subsequent depletion of spinal ejaculation center and contribute to the emergence of pathological pelvic congestion in the pelvic fat and the pelvic organs (hemorrhoids, colitis and prolonged constipation). Management is by reassurance.

## MASTURBATION

Masturbation refers to nonpenetrative sexual stimulation of a person's genitals often to the point of orgasm. The stimulation can be performed manually, by other types of bodily contact (short of sexual contact), by use of objects or tools or by some combination of these methods. The English word *masturbation* was introduced in the 18th century based on the Latin word, *masturbari*, alongside the more technical and slightly earlier *onanism*.

Masturbation or self-stimulation of genitalia is a common human behavior and is believed to occur in 90–94% of males and 50–60% of females at some point during their life time. A study from Gujarat in 1995 in adolescent girls revealed 30% of sample indulged in masturbation.

The capacity for sexual response is present from birth. Male infants have erections and vaginal lubrication has been found in female infants 24 hours after birth. Infants have been observed fondling their genitals; the rhythmic manipulation associated with adult masturbation appears at ages 2.5–3 years. Normally, it may begin at 2 months of age and peak at 4 years of age. The practice which resembles infantile masturbation is normal and child is discovering sexuality. The concept of infantile masturbation was suggested by Still in the early part of 20th century and has been widely recognized since then by the medical fraternity. Normally, the behavior stops on its own as child learns social norms and is gradually discouraged by caretakers. As this is a normal human behavior, it needs nothing more than reassurance to the anxious parents. It is highly preferable to use the term gratification disorder instead of infantile masturbation in view of the social stigma attached to this term and to alleviate parental anxiety.

As adolescents pass through puberty, sexual arousal occurs and they may masturbate. This is considered physiologic. Today, masturbatory act is considered as a healthy practice when done in private and an offence if done in the public in most of the countries. Masturbation is considered as pathologic during the following situations:

Excessive handling of genitalia in child less than 5 years may be due to low-grade urinary tract infection. It may be due to child requiring more soothing or requiring distraction. Such a habit can also be addressed by providing other activities for the child to engage with.

Age-inappropriate sexual knowledge, sexualized play or aggression, precocious or seductive behavior and excessive masturbation may be a sign of sexual abuse where a child may have been exposed to sexual activity or was sexually abused.

Compulsive masturbation—adolescent craves to masturbate even at school or in public place.

Adolescent may blame masturbation for weakness, fatigue,

acne. It may occur due to premature exposure to sexual content, delayed cognitive development and psychiatric disorders.

## Implications for the Pediatrician

- Encourage the parent to have positive sexual attitude. The parent should not show negative gestures or emotions when children touch their genitals during bath or changing diapers. Parents can use the opportunity to teach child the body parts.
- As the child matures into adolescent, parents and doctor should introduce topics like masturbation, night emissions and high-risk behavior.
- Ensure adolescent privacy in their rooms.
- Adolescents should be encouraged to have outdoor activities.

## IN A NUTSHELL

1. Assessment of puberty by SMR helps in the diagnosis of not only disorders of puberty and DSD, but also in disorders of growth and development and many systemic and genetic disorders.
2. Menstrual irregularities are common among school girls of 15–17 years. The most common menstrual problems reported among the school girls were dysmenorrhea.
3. It is normal for the adolescent to feel confused about the sexual orientation.
4. It is important for adolescents and adults to be comfortable with all aspects of sexuality (anatomic sex, gender identity and sexual orientation).
5. Teens should be given the opportunity to discuss issues of sexual attraction and orientation, masturbation, substance and alcohol use, safer sex, school, family and friends.

## Chapter 24.3

# Psychosocial Development

Yamuna S

Adolescents are different from children and adults in the way they respond to a stimulus from the environment. The ensuing behavior also differs, this is not species specific. Novelty seeking, risk taking, sensation seeking, peer directed activities are also common among the adolescents of other mammalian species. Such a commonality is supported by research in the neurodevelopment of brain. With the advent of finer neuroimaging modalities, study of the human brain either in response to a particular stimulus or during expression of a specific emotion has helped in identifying certain areas of the brain that respond in a unique manner during adolescence in comparison to the adult brain.

In contrary to the original belief, human brain is capable of morphological and functional transformation even in adulthood; this depends on the structural reorganization and the speed of flow of signals from one region to the other related area. Human brain makes numerous synapses in the first decade in congruence with the experiences gathered. Synaptic pruning and myelination during adolescence determine the neurodevelopment. Adolescent brain has plasticity to accommodate the experience based reorganization during adolescence to evolve into a mature adult brain which is known for its stability.

### Synaptic Pruning

All through childhood and adolescence, neural connections are made actively. Cortical regions of the brain are thickened with the synapses created. Gray matter volume peaks at 11 year in girls and at 12 year in boys. Thereafter, the synapses that are sparingly used are pruned with retention of the ones used more frequently. Thus, pruning reduces the gray matter volume by 50% and contributes toward an efficient functioning, enhances specialization of brain regions, cortical thinning progresses from back to front with the frontal lobes showing the structural changes last.

### Myelination

In addition to pruning, the nerve fibers undergo myelination that promotes faster nerve conduction from one region to a distant related region. The progress of myelination can be interpreted from the volume of the white matter; frontal and prefrontal cortex myelinate only after the teenage comes to an end.

### Role of Prefrontal Cortex

Prefrontal cortex and other frontal regions of the brain play a major role in the higher-order cognitive skills and executive functioning that are needed for goal-directed behavior like planning, response inhibition, working memory and attention. These skills allow an

individual to pause long enough to take stock of a situation, assess his or her options, plan a course of action and execute it. The connections between the frontal regions and the amygdala become denser during adolescence, thus enhancing the transmission of signals between the executive and the emotional regions of the brain. This emotional maturity is less stable during adolescence especially in the presence of social and psychological stresses that results in emotion-controlled impulsive outcomes.

Risk taking, novelty seeking and sensation seeking that are unique to mid-adolescence are being attributed to the lack of emotion-based impulse control. Risk taking escalates in the presence of peer group that endorses the same. Risk taking reduces in late adolescence with the maturity of the prefrontal cortex; adolescents become capable of response inhibition in accordance with their learning that impacts the cognition.

## THEORIES OF DEVELOPMENT

In the last century, many theorists had proposed major theories to understand the development process in a child. Few of them that stood the test of time are as follows:

### Freud's Psychosexual Theory

Sigmund Freud (1856–1939) proposed that the personalities of the children would be determined by the way their respective parents handle the initial sexual desires in early childhood. Freud based his proposal on the sexual activity and the pleasurable sensations associated with certain body areas. He categorized human life in five stages: oral, anal, phallic, latent and genital (**Table 1**).

Another part of Freud's theory focused on the consciousness. All basic instinctual, selfish urges that demand immediate gratification are termed as id; when their needs are not met, the babies develop a more realistic approach which determines the *ego*; when the babies internalize the parental rules and values, the *super ego* evolves. Thus, the battle between the high moral super ego and basic urge Id is moderated by the ego that sculpts a child into an adult with actions approved by self. In an adolescent, wanting to see a movie with friends is the desire of the Id, but going to a movie by cutting classes is against what is expected by parents is dictated by the super ego; thus, the adolescent is ready to go for a movie with friends without cutting classes is determined by the ego. When the Id and super ego clash, the adolescent is disturbed until his emotional maturity is achieved.

### Erik Erikson's Psychosocial Theory

Erikson proposed the development of the human through the entire lifespan from infancy to adulthood. He downplayed the role of sex and the unconscious mind but focused more on the social, interpersonal and cultural influences across the lifespan. He suggested that a child has eight developmental stages from birth to death (**Table 2**) with each stage having a unique challenge which

**Table 1** Freud's psychosexual stages and their features

Stage	Period of life	Features
Oral	Infancy	Pleasures associated with sucking, biting, etc. with the mouth; an infant mouths the objects that come on its way or at least sucks his own fingers for pleasure
Anal	Toddler	Focus shifts to anus when toilet training begins; vigorous toilet training results in habitual constipation
Phallic	Preschooler	Associated with genital stimulation and the sexual identification; genital exploration and self-stimulation are common activities between 2 and 6 years of age
Latent	School going kid	Sexual urges and interest were temporarily nonexistent; attention on acquisition of skills takes priority
Genital	Adolescence and later	Adult sexual interests and activities dominate; adult gender role and sexual behavior is either carried out or fantasized

**Table 2** Erik Erikson's psychosocial stages of development

Stage	Psychosocial crisis	Basic virtue	Age	Remarks	Example
1	Trust vs mistrust	Hope	Infancy (up to 1.5 years)	Stability and consistency of care makes the infant develop trust on the caretaker. Bowlby's theory of attachment is also similar where the bonding between the infant and the caretaker is qualified based on the availability of care and attention	An infant, who has trust on the parents at this stage, usually continues to communicate with them even during adolescence
2	Autonomy vs shame	Will	Early childhood (1.5–3 years)	Child is more mobile and gathers skills for self-care. If given time to learn skills like wearing one's shoes, the child feels independent; the absence of such a learning ends in shame	A child with self-care individualizes well during adolescence
3	Initiative vs guilt	Purpose	Preschool (3–5 years)	Children usually move out of home to interact with other children and other adults. They initiate conversation and plan games and activities. Parents may stop the child in a view to limit boundaries which can be perceived by the child as a <i>source of nuisance to others</i> with guilt	A child who has achieved this phase of development evolves as an independent adolescent capable of forming new friendships, associations and relationships with members outside the family
4	Industry vs Inferiority	Competency	School going kid (5–12 years)	Children gather skills and seek approval from others for the same. A balance between accomplishment and modesty is necessary. But frequent disapproval during this phase results in inferiority	An adolescent who enters his teenage years with a sense of accomplishment at least in one area of life is able to enter the search for his identity with a better self-esteem
5	Identity formation vs role confusion	Fidelity	Adolescence (12–18 years)	This is a major stage when an adolescent explores himself to find his identity in multiple domains like physical stature, academic, athletic, social, sexual, financial areas of life. He defines his role for adulthood based on the understanding gained after the search. The lack of formation of identity either due to delayed pursuit or due to absence of the quest results in role confusion	Every adolescent should go through this search and then conclude his strengths and weaknesses. If not, he either forecloses his identity based on inputs from others or continues to search with no end in sight
6	Intimacy vs isolation	Love	Young adult (18–40 years)	Young adults share their emotions, feelings and ideas with others with whom they enjoy commitment and attachment. Such intimate association promotes meaningful relationships. Absence of intimacy results in isolation, loneliness and depression	Good attachment with caretakers during infancy promotes a better understanding of the needs of an intimate relationship as the youth is capable of not only receiving but also giving love and affection
7	Generativity vs stagnation	Care	Adulthood (40–65 years)	This is the stage when adults give back to the society in a productive manner after completion of commitments to the immediate kin. Contribution to the society takes the upper hand	Involvement in useful activities outside home forms the major part of their daily routine. Only those youngsters who have enjoyed the previous stages are capable of reaching this stage. A person who has no strength to feel proud of might get stuck at the stage of identity formation with confusion about self
8	Integrity vs despair	Wisdom	Maturity (65 years and above)	Here the productivity comes down and counting the accomplishments maintains integrity. A look back on one's life is seen as success if the fulfillment is high; the absence of which makes the person feel hopeless with only meager time at hand	A well lived adult enjoys this phase with contentment

he termed as crisis. The way these crises are overcome determines the identity of the person.

### Kohlberg's Theory of Moral Development

According to Kohlberg, moral reasoning develops in three levels with six stages; each level being more capable of handling the dilemmas in real life than the previous one (**Table 3**). This is again a lifespan approach. Not all individuals are capable of reaching the highest stage of reasoning. This has been discussed in detail in Chapter 21.1.

### Piaget's Stages of Cognitive Development

Piaget (1896–1980) was the first to suggest that children are not less intelligent than adults, but they think differently from adults. Children are *little scientists* who constantly explore the world around them and understand the same. They progressed through four stages of cognitive development (**Table 4**).

#### Formal Operational Stage

This is the fourth and the final stage of cognitive development that begins with the onset of adolescence and lasts into adulthood.

**Table 3** Kohlberg's stages of moral development

Levels	Stages	Term	Features	Examples
Level 1 Preconventional morality (childhood)	Stage 1	Obedience or punishment orientation	Children follow rules to avoid punishment. Rules are seen as absolute and fixed. This is the stage where young children begin with. Few adults remain in this stage of moral reasoning	If I do not wear my uniform, I will be punished
	Stage 2	Self-interest orientation	As children grow older, they see that other people have their own goals. They question, "By doing this what do I gain? Will I be rewarded?"	Will I be appreciated for wearing my uniform?
Level 2 Conventional morality (adolescence)	Stage 3	Social conformity orientation	Social expectations and norms are understood by adolescence. Conforming to the expectations determines the good <i>boys, nice girls</i> label	Good boys and good girls wear uniforms to school
	Stage 4	Law and order orientation	By the time individuals reach early adulthood, they follow rules to maintain law and order and to respect authority	School authorities expect us to wear uniform, so we wear uniform every day
Level 3 Postconventional morality (adulthood)	Stage 5	Social contract orientation	At this stage, people understand that there are differing opinions about what is right and wrong; laws are there to maintain a social contract; if the rules do not concur with the value system, adults may not follow the same	Wearing uniform on all days is the norm; but wearing our religious dress on our festival days is not wrong
	Stage 6	Universal ethics orientation	Very few people develop this level of moral reasoning. They are empathetic and practice principles based on universal ethics regardless of rules and laws	School should have a code of conduct, so even if it is a festival, my principle would be to adhere to the code of conduct as I prefer doing it that way. I will wear uniform to school

**Table 4** Piaget's stages of cognitive development

	Stage	Age	Key features
1	Sensorimotor	0–2 years	Acquire knowledge through sensory experiences and manipulating objects, object permanence
2	Preoperational	2–7 years	Can view the world only with their point of view. Cannot take other's view and struggle with logic. Pretend play
3	Concrete operational	7–11 years	Capable of thinking with logic but rigid. Struggle with abstract and hypothetical concepts
4	Formal operational	11 upward	Enhancement of logic, able to use deductive reasoning, understand abstract ideas

Abstract thought process, logical thought, deductive reasoning, systematic planning emerge during this stage.

### Logic

Deductive logic is the ability to use a general principle to determine a specific outcome especially in hypothetical situations like study of Algebra.

### Abstract Thought

Adolescents are able to see and plan beyond the *here and now*; capacity to consider possible outcomes and consequences of current action evolves. For instance, smoking during adolescence can increase the chances of lung cancer in adulthood makes sense to an adolescent with abstract thought process.

### Problem Solving

Problem solving using a methodical logical way emerges; will be able to choose from multiple options keeping in mind the probable outcome. Let us consider a girl of 17 who is troubled by eve teasing on a regular manner while going to college. She would be able to see the options before her like either going with a group of friends or request her parent to accompany her or might think about taking another route and then choose the best option.

## PSYCHOSOCIAL, MORAL AND COGNITIVE DEVELOPMENT

Having recollected the theories behind psychosocial, moral and cognitive aspects of human development, let us see the specific issues that determine the adolescence. From the above it is clear that the adolescents are in the psychosocial stage of *identity formation, level of conventional morality and cognitive stage of formal operation*. The stage of identity formation would be dealt with in detail while the moral and cognitive development during adolescence has been addressed in the respective sections above. Let us also explore if the existing studies suggest methods to promote positive youth development.

As postulated by Erik Erikson in his theory on psychosocial development with eight stages covering the lifespan, youth should resolve two crises before evolving into a mature adult: (i) identity formation versus role confusion during adolescence and (ii) intimacy versus isolation in late adolescence and early adulthood.

### What is Identity?

Identity is a core construct in psychology because it refers to how a person addresses the question, "Who am I?" Identity is a social

science concept. S Sharma and M Sharma said, *identity is an umbrella term used throughout the social sciences to describe an individual's comprehension of him or herself as a discrete, separate entity*. Proponents of theories on identity (Erik Erikson, Marcia and Higgins) proclaim that identity is learnt, well organized and continues to be dynamic; personal introspection of one's identity has emotional consequences. Inculcation of clear and positive identity after a thorough exploration during adolescence builds self-esteem and promotes self-definition, thereby reducing the self-discrepancies, paving way to a smoother path to adulthood.

Identity can be organized into general, physical, psychological, social, sexual and spiritual domains; identity formation is a dynamic process that spans the entire life; processes involved in the development of identity are influenced by external factors like childhood experiences, environmental changes, parenting styles and biological factors (**Table 5**).

*Identity crisis* occurs when adolescents seriously question their essential personal characteristics, their views of themselves, their concerns about how others view them or their doubts about the meaning and purpose of their existence. The outcome of the exploration could either be healthy or may lead to confusion.

### Marcia's Identity Status Theory

It proposed two dimensions namely exploration and commitment that influence the identity formation. She suggested four identity statuses as possible outcomes of exploration of active questioning and search for adult roles and values (**Table 6**). Commitment to the decisions taken with the personal goals in mind including all domains of life determines the path to adulthood.

Exploration has two components that give opportunity to redefine as shown in **Flow chart 1**. While in depth exploration

**Table 5** Impact of early childhood experiences on the development of identity in an adolescent

Early experiences	Consequences	Remarks
Attachment with parents/parent figures	Securely attached children are capable of making sustained friendships and relationships. Children with insecure ambivalent and avoidant types of attachment have trouble in making and sustaining friendships and relationships	Contributes to social identity
Parenting styles	Authoritarian parenting results either in submissive adolescents or rebellious young people. Recipients of permissive parenting style lack direction and discipline. Adolescents who have been brought up with authoritative parenting style evolve into self-confident, self-disciplined individuals	Self-esteem, communication style, interpersonal relationships are related to the parenting style practiced at home. Determines the self-efficacy of the adolescent
Environmental chaos	Domestic violence, trauma due to emotional, verbal, physical and sexual abuse has long-term implications in the adolescents. Quality of parents' marriage, type of family either joint family or nuclear family or broken/separated family has specific consequences in adolescents. Socioeconomic status, dwelling places influence the acquisition of skills and practices	Emotional competence, emotional regulation, self-regulation, self concept, emotional efficacy are established in response to the diverse environmental influences
Biological factors	Whether the adolescents are living with biological parents or foster parents, illnesses and disorders including specific learning disorders, predisposition to mental illnesses like schizophrenia, bipolar disorders, physical challenges like club foot, hemiparesis, flaccid paralysis of limbs or diseases like asthma, thalassemia, etc. are significant in determining the process of identity formation in the adolescents	Illnesses stall the identity achievement

**Table 6** Marcia's four identity status

Dimensions	High exploration	Low exploration
High commitment	Identity achieved	Identity foreclosure
Low commitment	Identity moratorium	Identity diffusion

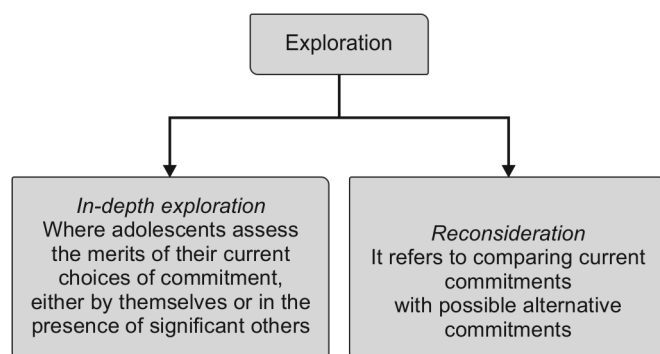

helps in self-understanding; reconsideration may result in confusion due to emergence of new alternatives. For example, an adolescent who moves into the university goes through reconsideration of his self-concept on friendships to make social associations in the new environment. Reconsideration helps in the adaptation to new developments in the environment in which we live.

### Higgins' Self-Discrepancy Theory

It focuses on the discrepancies that arise between the self domains and the standpoints from which they are viewed. Self domains are: (i) *actual self* (actually possess), (ii) *ideal self* (like to possess) and (iii) *ought self* (should possess). The standpoints from which they are viewed are: (i) *own* and (ii) *significant others* like parents and teachers. This results in six self-state representations: (i) actual/own, (ii) actual/other, (iii) ideal/own, (iv) ideal/other, (v) ought/own and (vi) ought/other. The nature and the extent of the discrepancies between the different selves affect the person's emotional vulnerabilities. For example, the discrepancies between:

- Actual/own and ideal/own are associated with *disappointment* and *dissatisfaction*

**Flow chart 1** Components of exploration in adolescents

- Actual/own and ideal/other are associated with *shame, embarrassment*
- Actual/own and ought/other are associated with *fear* and feel *threatened*
- Actual/own and ought/own are associated with *worthlessness* and *weakness*.

Some discrepancies are inevitable during the process of self-exploration as they help in formulating strategies to identity formation.

### Theory of Possible Selves

It focuses on those elements of self-concept that individuals could become, would like to become or are afraid of becoming. The latter is also known as *fear possible selves*. Empirical research has supported the idea that possible selves could be self-regulatory and can serve as roadmaps for one's behavior.

### Benzonsky's Identity Style Model

This model postulates that three processing styles can be depicted in adolescent identity formation.

1. The *informational style* involves the active searching and evaluation of identity-relevant information.
2. The *normative style* refers to the adherence to conventions, and dependence on the expectations and feedback of significant others when confronted with identity issues.
3. The *diffuse-avoidant style* denotes a tendency to procrastination in the handling of identity issues.

### Assessment of Identity

**Table 7** helps us in knowing the current level of identity formation in the adolescent. These measures not only facilitate discussion but also ensure transparency for other professionals to take over in the event of transition of care.

The results of the assessment would give a clear understanding about which aspect of identity formation should be focused during intervention. For example, choosing a career at 17 years of age; confusion between cinematography and information technology can be handled with in depth exploration of the adolescent with respect to preference of indoors versus outdoors, love for a desk job versus field activity, etc. This assessment helps in resolving the confusion with commitment to the choices made after exploration.

Physical deformity like a hemiparesis not only affects the psychosocial progress in the domains of autonomy and industriousness of childhood but also prevents the establishment of identity in certain domains due to discrepancies between actual/own and ideal/own, and actual/own and ought/own. The adolescent with *diffuse-avoidant identity style* with procrastination might postpone the process and stay confused, thus not be ready for intimacy during adulthood.

### Self-Efficacy

A person's behavior is under the reciprocal influence of the environment and his personal thought processes (cognitions) is the basis of the concept of *triadic reciprocity* as proposed by Bandura in the *Social Cognitive Theory* in 1990. Thus, an adolescent's academic performance (behavior) is influenced by his beliefs (cognitions) that are affected by the support provided by his parents, teachers and peers (environment).

Self-efficacy reflects one's beliefs about one's capacity to plan organize and execute a course of action to produce outcome. Thus, according to Bandura, *self-efficacy beliefs determine how people feel, think, motivate themselves and behave*. Self-efficacy can be seen in two ways: (i) task self-efficacy denotes the perceived ability to perform a particular behavior and coping self-efficacy denotes the perceived ability to prevent, control or cope with potential difficulties that might be encountered when engaged in a particular performance.

Self-efficacy can be assessed using quantitative and qualitative methods to understand the self-doubts in a person (**Box 1**).

#### BOX 1 Case vignette

*A student of class XII aspiring for a seat in a medical college through All India Premedical Test is preoccupied about his future and has not been able to focus on his preparation. On exploration he said, "I am very sure of my performance in the board exams as I am good in subjective approach to examination. I don't feel confident about the objective examination at AIPMT with multiple choice questions. So, I am pushing myself to accept the disappointment in the same." Thus, he is trying to use the coping self-efficacy to handle his self-doubt.*

### Emotional Competence

The capacity to understand one's emotions, others' emotions and handle the same in a socially approved manner is a topic of great interest, especially in the context of helping adolescents who have frequent anger outbursts. *Emotional intelligence* is related to one's innate potential to manage emotions which are related to traits like temperament and personality. *Emotional competence* is seen as a set of developed skills based on the early childhood experiences, emotional regulation of the family and also influenced by the self-discrepancies in identity which have a major emotional impact on the person. Competence can also mean that the skills can be inculcated with practice.

Saarni proposed eight skills. Consider a student of class XII on the day of his first examination; he is very abusive of his parents for nagging him to study and not being supportive. The features in the case mentioned are given within parentheses:

- Being aware of one's own emotions (anxiety, fear)
- Discerning and understanding others' emotions (parents' worry about his future)
- Using the vocabulary of emotion and expressions (I am anxious, please understand me)

**Table 7** Assessment of identity

Aspects of identity	Features	Example
Levels and domains of identity	Identity on a personal and social level. Domains such as physical appearance, athletic competence, scholastic competence, social acceptance, behavioral conduct, and global self-worth	Chinese Adolescent Self-Esteem Scales (CASES) to assess the self-esteem of Chinese adolescents in terms of seven aspects: social, academic, appearance, moral, family, physical/sport and general self-esteem
Identity statuses	One of four possible identity statuses: diffusion, foreclosure, moratorium and identity achievement	Quantitative and qualitative methods (like the identity status interview)
Identity dimensions	In-depth exploration, commitment and reconsideration	Utrecht-Management of Identity Commitments Scale (U-MICS)
Identity styles	Informational style, normative style and diffuse-avoidant style	Identity style inventory (revised)

- Having the capacity for empathic involvement (poor parents are worried about my future, after all I am their only son, they want to see me well settled).
- Differentiating internal, subjective emotional experience from external, emotional expression (I am absolutely anxious and panicky within, but I am showing it as anger, am I right?)
- Coping adaptively with aversive emotions and distressing circumstances (let me calm myself, so that I can approach the exams with a clear mind)
- Being aware of emotional communication within relationships (I can also cry on the parents' shoulder for relieving my anxiety)
- Possessing the capacity for emotional self-efficacy (I am sure I can handle the anxiety with deep breathing exercises over a period of time).

### HEADSS SCREENING TOOL

Adolescents are screened using the HEADSS tool (Goldenring and Cohen, 1998) to understand the psychosocial environment in which they live. **H**ome and environment; **E**ducation and employment; **A**ctivities; **D**rugs; **S**exuality; and **S**uicide/depression are the areas probed using a standard set of questions. Open-ended questions that encourage elaborate conversations are used to gather information. Closed-ended questions like, "*Do you live with parents?*" usually end either with a yes or no for an answer which gives very little information about the quality of the home environment.

### IN A NUTSHELL

1. Adolescence is a dynamic phase of life.
2. Identity formation is the key psychosocial concept during this phase.
3. Self-efficacy and emotional competence would help adolescents to scale through the phase with ease.
4. Pediatricians with the above understanding would be able to facilitate the adolescent to explore and reinvent himself.

# Section 25 HEALTH ISSUES IN ADOLESCENCE

Section Editor MKC Nair

## Chapter 25.1

### Factors Influencing Adolescent Health

Sukanta Chatterjee

The consideration of factors influencing adolescent health should include factors affecting physical health, mental health and social health, if not beyond. In comparison to other age groups, in the adolescent population, mental and social health issues are more important than physical health issues. The importance is not only in the incidence but also in the possibility of late detection of these health issues and their long-term impacts. In this context it needs to be mentioned. Lack of easy recognition between the normal variation and the disease state in nonphysical health issues is responsible for late intervention, both at family level and at health sector. Therefore, a clear understanding of the determinants or factors affecting adolescent health will be of great help to the readers in promoting health of the adolescents and also making detailed evaluation and treatment of their health problems.

The factors influencing adolescent health may be either unique for this age group, e.g., schooling or some of them may be common with other age group as we see them influencing health of adults, e.g., stress in human relations. The impact on health of any particular factor might differ in adolescents with a maturing mind and body in comparison to that seen in adults with a mature tolerant mind and an already matured body, e.g., an emotional stress might affect mental health more seriously in adolescents. In the discussion first of all, we shall mention the factors that operate on the health of an adolescent and thereafter the impact of each determinant along with interactions when more than one factor are operating simultaneously. The factors might influence health with positive impact called 'protective factors' or with negative impact or harmful effect called 'risk factors.' Finally the influencing factors may operate at different levels or situation like individual level, family, peers, school and society. Therefore, the factors affecting adolescent health to decide the ultimate outcome are complex:

- Factors operating at different level or situation, e.g., the individual, school, family and social situation
- Risk or protective factors
- Interaction of multiple factors both risk and protective for different duration and at different stages of mental and physical maturation.

In the entire write up the focus will be on these three points but the most ill understood is the last one that is interaction of

multiple factors which finally decides the health status. Therefore, the achieved health outcome may not be exactly predictable. Attempt is made to provide the evidence based information from the literature in less predictable situations rather than offering a conclusion. There is increasing evidence in research that the role of protective factors are major determinant to adolescent health outcome when they are getting more and more exposures to the risk factors in the process of modernization of the society.

#### FACTORS OPERATING AT DIFFERENT LEVELS

**Figure 1** shows the distance of different influencing factors acting on adolescent health. Closer the factor plotted here from the adolescent individual higher is the influence on the health that means, peers influence health of the adolescent more than the school or community. Each level has both risk and protective factors mentioned in details here:

- A. *Adolescent as an individual* The factors operating at individual level may be either protective or risk factors
  1. *Protective factors* Self-efficacy, self-esteem, spirituality/religiosity.
  2. *Risk factors* Gender and caste discrimination, off-time sexual maturation, substance abuse, absence of parents, feeling of hopelessness, mental depression, suicidal thought or attempts, physical or mental retardation, aggressive temperament, involvement in violence, homosexuality and slum dweller.
- B. *Peers* They play great role in shaping the adolescent health
  1. *Protective factors* Peer education, peer affiliation or acceptance, youth participation, youth organizations and many friends.
  2. *Risk factors* Negative peer culture, peer pressure or victimization, deviant friends and social isolation.
- C. *Family* The influence of family on adolescent health is traditionally recognized.
  1. *Protective factors* Family connectedness, appropriate parenting skill, monitoring 'how was the day' or taking report of the daily events and participation in family programs.
  2. *Risk factors* Overcrowding, addicted parent, parental conflict and violence, single parent particularly absence of father, hopelessness or mental illness in the family.
- D. *School or Work* Teachers and school environment offers significant influence on the health, particularly mental and social health of this population. Similarly employer, colleagues and work environment influence nonschool going working adolescent.
  1. *Protective factors* Positive counseling and parenting skills of teachers, school connectedness, good academic achievement.

	Health influencing factors
Adolescent	→ Peers → Family → School/Work → Community → Policy/Country

**Figure 1** Closer the distance from the adolescent, stronger is the influence on health

2. *Risk factors* Poor academic achiever, school drop outs, child labor, unemployed youth, excessive discipline, sexual abuse, physical violence, female gender and limited opportunities of sports and recreational activity organized by school.
- E. *Community* The modern society or community is presenting a host of opportunities and risks to the adolescents. Exposure with these opportunities depends on the awareness and affordability of the parents. The risk factors naturally attract adolescents if their influence is not protected by parental guidance.
  1. *Protective factors* Understanding and tolerant society, supportive environment for adolescents, interaction with previous generation, cultural heritage, scope of adolescent participation, optimal health and educational opportunities.
  2. *Risk factors* Nonsupportive community for holistic development of adolescent, permissive society for night clubs and pubs, sex and violence in media, lack of sports and recreation, migration, negative environment of lack of moral values and exploitation.
- F. *Policies and legislatures of the country* The influencing factors at this level are corruption, poor resources, transitional society, lack of existing policy for promoting adolescent health and invest on it.

Box 1 summarizes important health risk behaviors in adolescents.

#### BOX 1 Health risk behaviors in adolescents

1. **Food habit:** Skipping meals, overeating, junk food.
2. **Substance use:** Smoking, drinking, use of addictive drugs.
3. **Exercise and sports:** Inactivity, sedentary life style, risky sports.
4. **Violence and injuries:** Peer violence, sexual violence, keeping weapon, bike racing, no use of helmet and drunk driving.
5. **Sexual/Reproductive:** Dating, loss of romantic partner, early sexual debut, more than one sex partner, no use of condom.
6. **Social:** Conflict with law, police custody, and school dropout.

### Protective Factors in General

1. *Physical* Regular sports and physical activity, avoiding injury prone life style, healthy diet, early treatment of health risk factors and diseases.
2. *Emotional* Health conscious or awareness of positive health keeping, sense of happiness in mind, not feeling sad, no mental health difficulties, no evidence of mental health diseases like depression and no suicidal thought or attempt.
3. *Social* Satisfactory scholastic achievement, good peer relation, feeling connected with family, participation in social activity.

We shall now discuss few of the factors and situations mentioned above in details, e.g., relation with parents, teachers and peers, social status, mass media, education, gender, habits, lifestyle, behavioral issues, policies and legislation.

## FACTORS INFLUENCING HEALTH OF ADOLESCENTS

### Parents

Childhood relation with parents is all disclosure and dependent but the adolescent do not like to share everything due to confidentiality and privacy senses developing within them. Hence existing parent child relation changes to partial disclosure and partial hindrance. If there is anxiety and guilt feeling for this inevitable change of existing parental relation then it acts as a risk factor. Smooth adaptation to this situation leading to good personality development needs parental support in creating opportunities to discuss this normal transition for everyone.

The parenting style will also influence adolescent health. The four different types of parenting styles are mentioned here for understanding its influence.

### Authoritative Parenting

Here the parental expectation about child's performance is high but they provide opportunity to the child to discuss about the expectations and difficulties in performing it. The task and discipline imposed on the adolescent are explained properly and accepted logically to maintain by both. This is considered the ideal type of parenting. This parenting style helps the adolescent to understand about the effort and its outcome, ability in right decision making and be self-sufficient or independent.

Adolescents brought up in authoritative parenting style are mostly seen successful in expressing their opinion, happy with themselves, and supportive to others. They are liked and respected by their friends and become all-rounder adults.

### Authoritarian Parenting

The expectation of parents regarding the performance is high and the task and discipline imposed on the adolescent is rigid and noncompliance, which could be threatening. They do not get the opportunity to discuss the reason of the rule which even changes according to the wish and necessity of the parents, and hence the adolescent fails to understand what is expected and gets frustrated. Adolescents raised by this style live in a state of fear. They become less self-confident and socially withdrawn. They might defying the parents, leave home, consume drugs or alcohol, may initiate sexual behavior early, marry a partner whom parents do not approve and may prefer to live separately from their parents reaching adulthood.

### Permissive Parenting

Here the love and affection is more with lack of expectations to follow the discipline and indifferent of adolescent's performance or achievement. Parents always try to fulfill the demand of the child without attaching responsibility with it. They are very much emotional attached with the adolescent to see that their demands do not remain unfulfilled but do not take stock of activities in school or with peers. Adolescents brought up with this parenting style cannot control their emotion and unable to bear the responsibility of their work. They tend to become home sick or home dependent to continue with the environment of achievement on demand without performance. They often blame others without recognizing their own fault.

### Neglectful Parenting

It is one step forward of permissive parenting. The parents provide basic needs of the adolescent but do not care for their activity or performance. They are not emotionally attached with the adolescent and are indifferent of what has happened in the life of the adolescent throughout the day. At the end of the day they never ask the adolescent—"how was the day". The neglected adolescent might face serious problems at home or outside but parents are not aware till something tragic has happened. The adolescents often grow up with feeling of anger with the parents and might be less attached to home. They are more prone to sexual exploitation, addiction, violence and conflict with law.

### Teachers and School

The protective role of a teacher is to develop a good school connectedness by the adolescent. School connectedness is a state of happy feeling of the student that the teachers and other staffs of the school are interested and concerned in their studies and wellbeing. Teacher's indifferent role may act as a risk factor.

A school connected student is less prone to get involved in group violence, substance use like tobacco or alcohol, sexual debut or other risk taking activities. On the other hand they are better academic performers, have higher school attendance and involve themselves more in the school organized activities.

### *How to Promote School Connectedness?*

Six principles may be adapted by the stake holders of the school, the parents and the society to increase the feeling of attachment to the school by the students: (1) Provide an environment of involvement in decision making by the students, parents and the society in scholastic performance along with capacity building among staffs; (2) Offer educational and non-educational opportunities to ensure active participation of parents in the school life and studies of their children; (3) Empower pupils to understand and enjoy studies to stimulate their zeal of achieving academic excellence and impart the social and emotional skills required for active engagement in the school; (4) Offer a positive teaching learning method in the classroom to promote effective learning; (5) Provide the teaching and nonteaching staffs with quality training and resources required to promote the all-round development of the students not only in academics but also in social, emotional and cognitive domain; (6) Provide a supportive and trusted relationship among students, teachers, administrators, nonteaching staffs, parents and the society to encourage free exchange of opinion.

### **Peer Relations**

The relation with friends can have direct effect on health of an adolescent by influencing the behavior and attitude of peers, e.g., getting involved in drinking with friends or indirect effect by the perception of the adolescent about their friends' behavior and attitudes, e.g., initiate sexual activities thinking that others are doing it.

There are multiple components of peer relation which regulates an adolescent's interpersonal relation to regulate the mental health are: (a) general peer relations which imparts both positive impact (peer crowd acceptance or affiliations) or negative impact (peer victimization); (b) best friendship relations can also have both positive and negative impact, and (c) romantic relationship will have stronger positive or negative influence, e.g., break in romantic relation leads to greater negative impact on the health of the adolescent. Negative impact from above relations may lead to social anxiety and depression. An environment of peer crowd acceptance or affiliation, existence of satisfactory romantic relation and stable best friend relations help to develop confident personality and act as protection against depression. Failure to obtain acceptance from peer groups in general, strong differences in best friendship relations may lead to social anxiety on the other hand break in romantic relation, loss of best friendship relations or victimization by peers are more likely to lead to depression.

### *'Peer Crowds' and 'Best Friends'*

There are scientific publications indicating influence of peer relations in internalization of feeling of social anxiety and depression in the developing mind of adolescent. The term "peer crowds" means social relation of adolescent that happens within the peer group at large or the bigger group of adolescents with whom an individual relates regularly. Peer crowds may be a reputation-based group of similar individuals who might or might not mix together very often. An adolescent may mix with a peer crowd to seek support and acceptance from them. Peer crowd may be a high-profile, good image group known as *Hot Shots*, a sports-oriented group or *Athletes*, an academically accredited group or *Brains*, a group that protests against social norms called

*Nonconformists*, a defiant behavior group having conflict with law, e.g., *Burnouts* or *Druggies* and a group of misfits who remain indifferent or *Loners*. *Hot Shots*, *Athletes* and *Brains* represent high-status groups or crowds, whereas *Burnouts*, *Nonconformist* and *Druggies* represent low-status groups or crowds. Peer crowds are different from adolescents' smaller peer network or best friendship. Almost all teenagers have one or few best friends who mix with the same peer crowd.

### *'Peer Pressure' and 'Peer Affiliations'*

Peer victimization may be overt victimization like threats or physical violence, or relation victimization like spreading rumors, discontinuation of friendship and social boycott. Overt victimization is more commonly seen in boys than in girls although the occurrence of relational victimization is more common than overt victimization among adolescents. At early adolescence overt victimization affects mental health more than relation victimization; however, in older adolescents relation victimization might influence mental health more than overt victimization leading to loneliness, low self-esteem and depression. Peer affiliation may be sought from peer crowd or from best friends.

### *How to Overcome Peer Pressure?*

1. Encourage adolescents to develop positive self-esteem and good peer relation to withstand or neutralize the impact of negative peer relations or pressure.
2. Establish good relation with adults who are important in the life of the adolescent like teachers, parents, relatives and family friends.
3. Encourage diverse relationships and support group among friends, at school and in society, by involving them to play and work together.
4. Organize parent education programs along with their adolescent children.
5. Teach adolescents the skill to cope with negative impact of behavior and take right decisions.
6. Teach adolescents how to say 'no' in peer pressure retaining the relation in future.

### *Best Friendships*

Successful establishment of intimate friendship relations increases the interpersonal skill to develop good relationship in the society and reduces the negative impact of diminished acceptance among peer crowd. Main source of support in the society to an adolescent is his friends. It is seen that close friendship with support and empathy act as protective factor for mental health for adolescents by reducing social anxiety. Good psychosocial development and a positive self-esteem come up through best friends' support. Friendship relation can have its negative effect also like conflict, violence, peer victimization or relationship termination. They may lead to problem of school adjustment, increases interpersonal conflicts, feeling of stress, anxiety and depression.

### *Romantic Partners*

During late adolescence, adolescents in late teens develop more interest and inclination towards romantic relations than with close friends, parents, and relatives. An established romantic relation acts as a strong positive factor for mental health of adolescents. On the other hand, stress in romantic relation will increase the incidences of depressive symptoms than that of adolescents without having romantic partners. Break of romantic relation will have higher negative impact on adolescent's mental health than that seen in break of best friendship relation. An adolescent with depression finds it difficult to develop romantic relations.

### Competitive and Cooperative Relations

The current modern society presents a competitive relation among schoolmates in adolescents. The competition remains healthy with attempts of individual achievement with cooperation and sharing of resources without restricting the interest of others. Compromising the access to resources for peers in the interest of competitive achievement leads to selfish and jealous personality. These adolescents fail to develop trusted relations with the contemporary members of the society. An atmosphere of cooperation rather than unhealthy competition leads to greater individual achievements and friendship relations.

### Social Status

With the increase of available opportunities in the society, the risk factors are equally accompanying them. Education, social relations and employment options may be the major ones looked after by the adolescents. Risk of not getting the best education may be economy or lack of awareness of parents of it. Risk involved in developing relations and getting employment are becoming complex difficult to handle by the adolescents themselves. Low socioeconomic status offers adolescents less opportunities or protective factors and more risk factors since parents may not be aware of them or may not be able to provide quality time to negotiate the counseling skill to present a risk prone situation in a protective manner. Parents may have more stressors in the society to earn their livelihood and may adopt an authoritarian parenting at home to minimize stress at home leaving less scope to understand when their offspring are exposed to more risk factors. Higher socioeconomic status provides them more opportunities or protective environment due to parental awareness about the resources and affordability. The risk factors are minimized since the less stressed parents are more likely to be connected to the adolescents. Although this is the trend as evidenced in the research but not the rule since multiple factors influence to decide the health outcome.

### Social Learning and Social Control

There are evidences that social learning has greater impact on adolescent health than that of social control system. Social learning means what adolescent learn to adapt by seeing others doing it whereas social control means the restrain imposed by others which is not practiced by the imposer. If friends are involved in smoking or alcohol use or the same experience comes from the family, e.g., father is a smoker then adolescent are more likely to adapt these habits in spite of restrain or control efforts from the society. Social or family control to prevent these negative practices is statistically less effective when adolescents are exposed to negative learning situation in the family or with friends. It is seen that the attachment to mother and father and regular monitoring by parents reduces the risk of substance use in adolescents significantly but this influence is statistically less significant if compared with the influence of learning experience by the adolescent in the similar field. Similarly, a westernized or modern urban society which is permissive to pubs and dating culture for adolescents provides more learning experiences for alcohol use and sexual experimentations hence family restrictions may be less effective to protect them.

### Mass Media

Access to mass media, particularly electronic media including internet, is rapidly increasing amongst adolescents. It may significantly affect the physical, mental and social health by influencing their behavior. Commercial mass media usually excite the bioemotional desire of the individual. Social norms, religion and culture restrain it. A given type of stimulus from mass media,

commercial or sexual, may have more serious effects on the immature adolescent mind than that of an adult mind. Exposure to media is inevitable and also desired since it provides many protective factors in the form of knowledge. Adolescents having media literacy understands the motive of the publication sponsor thereby develop the capacity to minimize the risk at exposure.

### Media Literacy

Getting adolescents to actively analyze and think about the media regarding their motive, commercial interest and its trustworthiness develops awareness of the potential harmful or beneficial effect a media. This is media awareness or literacy. There are media awareness development websites hosted by noncommercial professional organizations such as the American Academy of Pediatrics and Canadian Pediatric Society such as [www.cps.ca](http://www.cps.ca) or [www.media-awareness.ca](http://www.media-awareness.ca)

### How to Minimize the Risk from Media Exposure?

1. Encourage family members to watch the media together and look for or create opportunities to discuss with the adolescents the positive and negative aspects of it. Parents can facilitate in their children the skill of critical analysis to understand the difference of reality and fantasy in context of what is being shown, e.g., product advertisement, violence and sex.
2. Placement of media displayer like television, computer with net, video game devices, etc. at a central place in the house having physical and password access to all.
3. A home rule of only 2 hours of television and computer access by the adolescents should be maintained by parents and other adult care givers.
4. Teenagers should be given the opportunity to make choices of programs to be accommodated in this 2 hours slot in consultation with parents. This will regularly offer the scope of helping the adolescents make their right choices through discussion, why some programs are not suitable for them. Praising them on making good choice brings confidence in adolescents to make similar choices in future.

### Education

Education empowers adolescents. It reduces risk exposure and increases protective behaviors. There is no evidence in the literature that sex education increases the early sexual experimentation or unwanted pregnancy. Adequate sex education will increase the capacity of protection for the sexual and reproductive health. Good academic grades delays sexual debut in contrast to school dropout or detainers.

### Gender

Sex is biologically determined; gender is attributed by the society. Gender indicates the behavior, roles and responsibility expected to be observed by a man or a woman in the society. Hence it may differ from country to country or amongst localities, e.g., a womanly behavior of a conservative family of rural India may not match with that of a family of a metro city. The gender role constructed by the religion, culture, family values and further modified by mass media, economic and political factors. In Indian context boys and girls in adolescent age are allowed to have different sets of exposures and opportunities in the family and the society. This makes them receptive to variable risk and protective factors due to gender alone. Therefore, all components of health like physical, mental and social health may have a different health outcome in boys and girls although they are brought up in the same family. Access to health services and control over health resources that help in protection and promotion of health, may also be controlled by gender. It affects the health of the women and also the children born of and brought

up by them. The sexual behavior is also regulated by the balance between the preset gender standard or expectation and the existing permissibility of the society. Bioemotional instinct of human try to distort the society set gender specific behavior. Mass media helps to increase the social permissibility for this desired distortion to set an accepted new standard. That is how gender behavior changes with time in the same society. Girls are more vulnerable than boys by social and biological reasons. On the other hand, boys in India are having less family and socially accepted opportunity to access the existing sexual and reproductive health services in contrast to girls.

Gender equality means equal access to and distribution of available benefits and resources irrespective of being men or women. It does not take care of the difference in the need for men and women. Gender equity, on the other hand, recognizes that men and women have differences in their health needs, therefore, it is rational for better health outcome that these differences be addressed while allocating resources and access to services in relation to the gender. It means that men and women should be treated with gender equality where they have common needs but where differences in need exist it should go by gender equity. Gender discrimination leads to behavior restrictions, less education, nutrition deprivation, early marriage, domestic violence and sexual offence on girls. Factors promoting gender discrimination in favor of male are seeing pornography, belief that their friends are sexually active, addiction, possession of weapon and doing job. Factors influencing gender discrimination negatively in girls are absence of father, unstable family.

### Gender Tool

To ensure the gender equity where the difference in the health needs exist among adolescent boys and girls, World Health Organization developed an action strategy called *Gender Tool* for healthcare providers and policy makers.

### Habits

Habits are long-term practices maintained by an individual usually offering pleasant experience. Adolescent habits in eating, physical activity, risk taking, substance uses are going to influence health. Taking adequate balanced diet regularly and doing optimum sports and activities act as protective factor. Over eating, junk food, lack of physical activity, risky sports and behaviors, getting involved in violence and alcohol or tobacco use will have negative impact.

### Lifestyle

Medical world has already recognized the term *lifestyle diseases* indicating causal relationship of disease and lifestyle, e.g., sedentary lifestyle may lead to obesity. Adolescent lifestyle may have early or immediate health impact in the adolescent age, e.g., physical injuries or it may have long-term impact in adult life, e.g., acquiring AIDS, obesity and hypertension. Lifestyle may affect all components of health like physical health, mental health and social health; each component can have short-term or long-term impact. Lifestyle of a teenager may be influenced by his food habits and nourishment, sports and activities, body weight, addiction, mental health and sexual health. Lifestyle is regulated by the family and social opportunities and restrains along with individual instinct. Therefore family practices, education environment and social exposure along with adolescent's choice act as regulators to decide the final outcome regarding lifestyle. Each setting can have either positive or negative impact on health.

### Behavioral Issues

Unhealthy behaviors are often acquired in adolescence and leads to adult life morbidity. Common health risk activities seen

in Indian adolescents are adventurous sports, substance use like tobacco, alcohol, drugs and sexual experimentation. Risky sexual behaviors and substance use often accompany each other. There are many intervention strategies developed to combat an individual risky behavior of the adolescent but strategies that work to combat the influence and interaction of multiple risk behaviors need to be worked out. The wider social determinants of health (protective and risky behaviors and their interaction) must not be overlooked. These are beyond the microenvironments or the singled out risk behaviors mentioned above. Therefore, it is important to remember the multiple determinants prevailing in broad social environment that influence the behavior of adolescents while framing government policies and intervention strategies. There is little evidence that increasing the price of alcohol reduces binge drinking on the other hand, smoking initiation is reduced by increasing the price of tobacco. The impact of intervention programs at mass media on prevention of smoking initiation or cessation among adolescents is good and evidence based but alcohol consumption and risky sexual behaviors are little influenced by mass media programs.

### Policies and Legislations

Comprehensive adolescent health policy needs to be developed by the legislative authority. There is enough evidence that investment on adolescent health, both at preventive and promotional strategies at national and policy level helps in obtaining positive results on adolescent health. Sales restriction of tobacco and alcohol does not reduce the substance use since adolescents buy them through illegal route.

#### IN A NUTSHELL

1. Mental and social health issues in adolescents are more important than physical health issues yet the healthcare providers are traditionally trained and comfortable to deal with the physical health problems rather than the mental health or social health issues.
2. Lack of easy recognition between the normal variation and the disease state in nonphysical health issues is responsible for late intervention, both at family level and at health sector.
3. The impact on health of any particular factor might differ in adolescents due to a maturing mind and body in comparison to that seen in adults with a matured body and tolerant mind.
4. The factors might influence health with positive impact called *protective factors* or with negative impact or harmful effect called *risk factors*.
5. There are increasing evidence that the role of protective factors are major determinant to adolescent health outcome when they are getting more and more exposures to the risk factors in the process of modernization of the society.
6. The authoritative parenting styles is considered ideal for adolescents.
7. Peer crowd affiliation and romantic relation, work as strong protective factor.
8. *School connectedness* acts as a protective factor. It is the belief by students that adults and peers in the school care about their learning as well as about them as individuals.
9. Social learning has greater impact on adolescent health than that of social control system.
10. With the increase of available opportunities in the society, the risk factors that are accompanying them also increase.

## Chapter 25.2

# Adolescent Nutrition

Preeti M Galagali

Nutrition is a key determinant for ensuring optimal health in adolescence. Adolescence is one of the most rapid periods of growth, second only to infancy. Hence, the nutritional requirements are greatest in this phase of life. Psychosocial developmental changes in the form of autonomy, identity issues, body image concerns, experimentation and peer affiliation have a significant effect on dietary intake in adolescence. Adequate nutrition in adolescence can ensure a healthy transition into adulthood. Adolescent malnutrition; both over and undernutrition has deleterious effects on health over the entire life span. It even has an intergenerational effect on the health of the future progeny.

With the change in the socioeconomic milieu in India, there has been a change in lifestyle of the population. Population explosion, demographic changes, rapid urbanization, globalization and media boom have resulted in significant changes. These lifestyle changes include *nutrition transition* from traditional whole grain diet to adopting modern processed, refined ready to eat diet and increase in sedentary activities like television and computer usage. Aggressive advertising of junk food and beverages especially targeted at the youth has also contributed to an increase in their consumption. Habits formed in adolescence persist into adulthood. Unhealthy nutritional practices are one of the important contributors to the emerging epidemics of obesity, anemia, hypertension, hyperlipidemia, hypercholesterolemia, type 2 diabetes mellitus, eating disorders, caries and osteoporosis in the young.

## ADOLESCENCE: A NUTRITIONALLY VULNERABLE PERIOD

Adolescence is a nutritionally vulnerable period as the physiological increase in nutritional demands may not be met adequately. This is because dietary choices and lifestyle in adolescence are influenced to a great extent by external factors like quality and quantity of food available, peers and media. In addition, adolescents may make unhealthy dietary choices due to immaturity of the prefrontal cortex of the brain that is responsible for judgment and decision making.

Adolescence is characterized by hormonal surges and sexual maturation resulting in dramatic changes in height, weight, muscle mass and fat distribution. A poor dietary intake in adolescence results in delayed sexual maturation, decreased lean body mass and stature, decreased cognitive ability and poor school performance. The following anabolic changes in physical growth during adolescence require increased intake of energy and nutrients.

- Gain of 15% of adult height and 50% of adult weight
- Growth spurt with an average annual increase of 9–10 cm in height and 8–10 kg in weight
- Gain of 45% of adult skeletal mass
- In boys, testosterone promotes an increase in lean body mass while in girls, increase in estrogen and progesterone result in increased fat deposition. In adolescent boys, body fat accounts for 15% of total body weight and in girls, 19–23%. Also, an increase in growth hormone and insulin like growth factor-1 result in *physiological* insulin resistance during puberty that leads to increased adiposity.

With emergence of autonomy and independence in early and middle adolescence, the influence of family decreases and the dietary and physical activity patterns are determined to a large extent by peer attitudes, behavior and by media messages. In this period, concrete thinking is the predominant cognitive ability that compromises the ability to link current healthy behavior to future adult health. Immediate rewards in the form of improved body appearance, peer acceptance and taste preferences govern food choices and behavior. If proper guidance and nutritional counseling are not given to adolescents, unhealthy eating behavior and habits may easily set in. In later adolescence, as the identity consolidates, abstract thinking develops and peer influence wanes away, lifestyle choices are made according to one's own values and attitudes.

## NUTRITIONAL STATUS OF ADOLESCENTS

Globally, 85% of adolescents live in developing countries of South East Asia and Sub-Sahara. Stunting, undernutrition and micronutrient deficiencies in adolescents are common in these regions due to poverty, inadequate nutrition, helminthiasis and poor growth in early childhood. Undernutrition in early life is mainly due to protein energy malnutrition and infections. Early marriage and pregnancy further compromise the nutritional status of adolescent girls. This in turn triggers the intergenerational cycle of malnutrition as the undernourished adolescent girl gives birth to a low birth weight or premature baby who is susceptible to increased morbidity and mortality throughout the life span. According to 2011 census, the median age of marriage in India is 21 years. Fifty percent of adolescent girls in rural areas and 33% in urban areas are married. Low birth weight accounts for 22% of all newborn births. A change in dietary practices in the form of increased consumption of energy dense, nutrient depleted fast food especially amongst the higher socioeconomic strata has led to an increase in overnutrition in adolescence in the developing countries. Decrease in physical activity has also contributed to an increase in obesity.

## Stunting

Stunting is defined as height less than 3<sup>rd</sup> percentile on height chart for that particular age. Stunting in adolescents indicates chronic energy and nutritional deficiency. It results in decreased physical ability and risk of obstetric complications like obstructed labor due to contracted pelvis. In developing countries, the prevalence of stunting in adolescence ranges from 12% to 67.3%. According to National Nutrition Monitoring Bureau Report 2000, 39% of the Indian adolescents are stunted and 24.1% of the married adolescent girls had a height less than 145 cm. It is controversial as to whether increased nutritional intake in adolescent period would spur up the peak height velocity during adolescence and allow for *catch up* growth. It is proposed that height in adolescence and adult period is determined by genetics and adequate nutrition in the first 2–3 years of life that are critical to growth. Increased intake in adolescence for those who are undernourished may in fact promote the onset of obesity. In the undernourished adolescents, there is usually a delayed onset of menarche and this may perhaps permit more time for *catch up growth*. Secular trends over twenty years from 1975 to 1996 indicate that there has been an increase of 2.5–3.5 cm in height and 1–1.5 kg in the mean weight of Indian adolescents.

## Underweight

According to WHO, the best indicator for *thinness* in adolescence is a body mass index (BMI) that is less than 5<sup>th</sup> percentile for that particular age. Demographic and Health Surveys (DHS 2002–2007) indicate that prevalence of underweight in girls aged 15 to 19 years is from 27% to 47% in the South east Asian and Sub

Saharan regions. The prevalence of undernutrition in Indian adolescents is given in **Table 1**. Overall prevalence in adolescence is 53%. More boys than girls are underweight and the prevalence of undernutrition decreases with age in adolescence. According to National Nutrition Monitoring Bureau (NNMB) 2000 report, 77.6% of 11-year-old boys were undernourished compared to 44% at 17 years. In girls, 62.7% of 10-year-olds were undernourished compared to 16.4% at 17 years.

### Micronutrient Deficiency

Globally, iron deficiency is the most common nutritional deficiency and cause of anemia in adolescence. In the developing countries, the prevalence of anemia in adolescent girls aged 15–19 years, ranges from 49% to 68%. The prevalence of anemia in Indian adolescents is given in **Table 2**. The overall prevalence is 55%. It is more in girls than boys. Anemia is more prevalent in the married adolescent girls and those living in rural areas and belonging to scheduled castes and tribes. Gender discrimination, poor dietary intake and early pregnancy contribute to increased prevalence of anemia in girls. Nutritional anemia directly contributes to nearly 24% of maternal mortality. In 2007, a review of 11 studies from India evaluating nutritional status of school children from 6 years to 18 years from middle and high socioeconomic strata revealed that even overnutrition coexisted with micronutrient deficiencies. In this review 19–88% of the study population was anemic and nearly 100% had folate deficiency while prevalence of riboflavin, niacin, vitamin C, vitamin A and vitamin B<sub>12</sub> ranged from 40% to 60%.

### Overnutrition

Rapid urbanization of the developing world has concomitantly resulted in an increased prevalence of overweight and obesity. Overweight is defined as being between 85<sup>th</sup> and 95<sup>th</sup> centile on BMI sex and age related charts and obesity as being above 95<sup>th</sup> centile. The prevalence of obesity in the Indian adolescents is given in **Table 1**. Secular trends reveal that prevalence of obesity has increased from 9.8% in 2006 to 11.7% in 2007 in urban adolescents aged 14–17 years. There was a two fold increase in risk of obesity in those watching television for more than 3 hours per day. The risk increased by four fold in the high socioeconomic strata. Adolescents who indulged in outdoor games for more than 6 hours per week or did household activities for more than 3 hours per day had a lower prevalence of overnutrition. In the 2007 review, the

prevalence of overweight varied from 8.5% to 29% and of obesity from 1.5% to 7.5% in urban adolescents.

### Energy and Nutrient Intake

National Nutrition Monitoring Bureau 2006 report states that most Indian adolescents consume 66% of the recommended caloric intake and 32–45% of recommended dietary allowance (RDA) of iron leading to widespread prevalence of undernutrition and anemia. Sixty six percent were consuming less than 70% of RDA for riboflavin and vitamin A. The adolescent diets were also deficient in protein. A 2007 study done in six rural blocks revealed that in adolescent girls, the intake of milk and milk products, pulses, vegetables and fruits was grossly inadequate. Higher socioeconomic strata consumed an energy rich diet with increased intake of fats and sugar and decreased dietary fiber. Over the past two decades (from 1975 to 1995), the extent of severe deficit with respect to energy (< 50% of RDA) has decreased from 21% to 9% in adolescent boys and 14% to 5% in girls.

### DIETARY RECOMMENDATIONS FOR ADOLESCENTS

Adolescent dietary recommendations include daily energy and nutrient requirements to maintain health and to support ongoing growth and development. Recommendations also address how food and beverages should be chosen to fulfill the normal dietary requirements. Macronutrients namely carbohydrates, proteins and fats provide energy while micronutrients like vitamins and minerals are important components of enzymes and hormones. Recommended dietary allowances (RDAs) are the quantitative levels that meet the needs of nearly 98% of individuals in a particular life stage and sex group. Nutritional requirements in adolescence vary according to current weight, age, sex, pubertal stage and physical activity level. Current RDAs for Indian adolescent boys and girls along with recommended dietary portions are given in **Tables 3 to 5**. National Institute of Nutrition, Hyderabad in 2010 framed the Dietary Guidelines for Indians. These guidelines recommend eating a variety of food from different food groups, increasing the intake of fruits and vegetables, moderating the intake of edible oils, salt, ready to drink beverages and processed foods and on doing regular exercise (See Section 22). The guidelines also recommend 60 min of moderate physical activity for adolescents on a daily basis.

### Energy

To maintain optimal weight, energy intake must be balanced with expenditure. Energy is expended in doing daily activities, for growth and for maintaining basic metabolic rate. As adolescent boys have a higher increase in height, weight and lean body mass compared to girls, their energy needs are greater. Energy intake increases with increased levels of physical activity.

### Micronutrients

The requirements for iron, zinc and calcium are higher during adolescence compared to second decade of life when the growth is almost complete. Vitamin needs steadily increase from childhood into adolescence.

### Iron

Iron needs are increased in adolescence as there is a higher production of myoglobin and hemoglobin due to an increase in lean muscle tissue and red cell mass. In girls, iron is also required to cover monthly menstrual losses of approximately 30–40 mL. Diet rich in iron include green leafy vegetables, legumes, dry fruits, meat, fish and poultry. Bioavailability of iron is poor from plant

**Table 1** Nutritional Status of Indian adolescents aged 15–19 years

Nutrition status (BMI)	Undernutrition (< 18.5)	Normal	Overnutrition (> 25)
Female	46.8%	50.8%	2.4%
Male	58.1%	40.2%	1.7%

Abbreviation: BMI, body mass index.

Source: National Family Health Survey-3 (NFHS-3), 2005-06.

**Table 2** Prevalence of anemia in Indian adolescents aged 15–19 years

Severity	Mild anemia*	Moderate anemia*	Severe anemia*	Any anemia
Girls	39.1%	14.9%	1.7%	55.7%
Boys	16.7%	12.1%	1.4%	30.2%

\*Anemia defined as mild, moderate, severe, and any as follows:

Girls (Hemoglobin: 10–11.9 g/dL, 7–9.9 g/dL, < 7 g/dL, < 12 g/dL) and

Boys (Hemoglobin: 12–12.9 g/dL, 9–11.9 g/dL, < 9 g/dL, < 13 g/dL).

Source: National Family Health Survey-3 (NFHS-3), 2005-06.

food. Eating food rich in vitamin C like *amla*, guava and citrus fruits along with an iron rich diet increases the intestinal absorption of iron. Tannin in tea inhibits the absorption of iron and is to be avoided especially immediately before, after or during meals. Poor dietary intake results in anemia that impairs growth and cognition and leads to fatigue and increased risk of infections.

### Calcium Intake

Calcium intake is important as there is maximum bone mineral accretion in adolescence and nearly half of the peak skeletal mass is accumulated in this phase. Increased calcium needs must be entirely met by dietary intake. Poor dietary intake will result in long-term risk of osteoporosis. Calcium is found in dairy products,

**Table 3** Recommended dietary allowances for adolescents

Age (years)	Girls						
	Calories	Proteins (g)	Fat (g)	Calcium (mg)	Iron (mg)	Zinc (mg)	Magnesium (mg)
10–12	2010	40.4	35	800	27	9	160
13–15	2330	51.9	40	800	28	11	210

13–15	14	2.5	5	1.5	1	2	1	4	9
16–18	15	3	5	2	1	2	1	6	10

Source: National Institute of Nutrition, ICMR Guidelines 2010.

fish, spinach, ragi, broccoli, turnip, custard apple and almonds. Along with calcium, adequate Vitamin D, parathyroid hormone and doing weight bearing exercises are essential to maintain bone mineral density. Contraceptive usage, alcohol abuse and excessive soft drink consumption in adolescence impairs calcium absorption.

### Zinc

Zinc has an important role in protein synthesis and general growth and maintenance of tissues. Dietary sources include meat, dairy products, nuts and whole grains. Inadequate intake results in growth failure, delayed sexual maturation, loss of taste and appetite and mental lethargy.

### Folate and Vitamin B<sub>12</sub>

Folate and Vitamin B<sub>12</sub> are required for formation of red blood cells. Folate is obtained from green leafy vegetables, legumes, whole grain cereals and liver. Vitamin B<sub>12</sub> is obtained from non-vegetarian food, eggs and dairy products. Deficiency of Vitamin B<sub>12</sub> and folate in adolescence results in megaloblastic anemia. Folate is essential for replication and translation of DNA and thereby for cell division and protein synthesis. Its deficiency in the periconceptional period results in neural tube defects in the fetus. Vitamin B<sub>12</sub> deficiency also results in neurological damage.

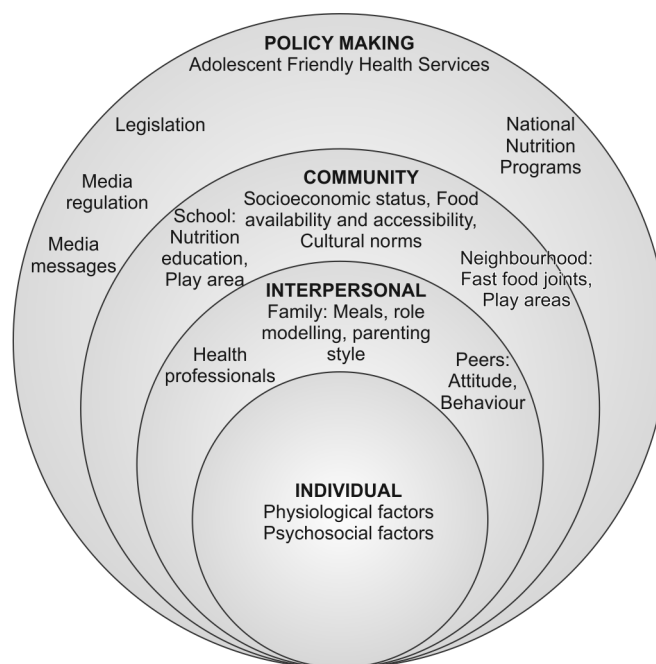

Pregnant and lactating adolescents have increased requirements of all micronutrients. Only 51% of households in India consume iodized salts. Iodine deficiency disorders contribute to 90,000 still births and neonatal deaths annually. They also result in mental retardation and impaired cognition. Adolescents who follow a strict vegan diet and those on drugs like alcohol and tobacco may require dietary supplements. Vegetarians may be at an increased risk of protein, vitamin B<sub>12</sub>, vitamin D, iron, zinc, calcium and omega-3 fatty acid deficiencies.

## FACTORS AFFECTING ADOLESCENT NUTRITION

Recent research has proved that socioecological factors affect adolescent health and behavior including dietary intake, level of physical activity and media usage. The socioecological determinants of adolescent nutrition are shown in **Figure 1**. Knowledge of these factors is important in policy making and planning of effective nutritional health programs at the individual and the community level. These determinants operate at multiple levels and are as follows.

### 1. Individual Level

Both physiological and psychosocial factors work at the individual level to determine dietary intakes. Physiological factors include sex, stage of adolescent development, disease and health status. Boys have larger appetite than girls and have also increased physical activity levels. Mid adolescents get easily influenced by the peer group. Those with poorly controlled chronic diseases like tuberculosis, asthma, depression or connective tissue disorders may have poor appetite. Those with diabetes mellitus may have dietary restrictions. Psychosocial factors such as knowledge, attitudes, and beliefs related to food, existing meal and dieting patterns and body image concerns influence dietary patterns. Adolescents especially girls who are excessively concerned about maintaining a *zero figure* may have low energy and nutrient consumption. Many adolescents are in the habit of skipping meals especially breakfast and a few prefer to eat only sweet or oily food. Increased media usage promotes sedentary behavior and weight gain.

**Figure 1** Socio-ecological model of determinants of adolescent nutrition

### 2. Interpersonal Level

Family peers and health professionals influence dietary intake in adolescence. Authoritative parenting style, parental encouragement and modeling, emotional connectedness, family meals, home resources for healthy eating and physical activity and cooperative siblings promote adequate dietary intake. Peer groups that promote intake of unhealthy junk food, fast food, in between meal snacking, soft drinks, colas and alcohol influence the adolescent in adopting the same. Fad diets, excessive dieting and dissatisfaction with current body image may also be reinforced by friends. In middle adolescence, the effect of family wanes and the influence of peers on behavior increases. Health professionals can negate the effect of such influence by imparting science based anticipatory guidance and counseling to adolescents.

### 3. Community Level

Availability and accessibility of processed food and junk food determines its intake. Adolescents belonging to lower socio economic status and in rural areas consume diets poor in energy, proteins and minerals. The consumption of junk food by adolescents increases if their college and school canteens supply such food items. Educational institutions that provide effective evidence based nutrition education play a big role in promoting healthy eating habits and attitudes. A large number of cheap fast food joints in the immediate neighborhood encourage consumption of energy dense nutrient poor food and beverages. Glossy junk food promoting media messages especially by celebrities should be banned or censored. Many media messages encourage the adolescent to adopt unhealthy body images like *thinness* in girls or *muscularity* in boys. Media literacy is the need of the hour. Social norms like celebrating *achievements and successes* by holding high caloric feasts and meals may also influence dietary consumption of adolescents. Safe playing areas would promote physical activity. Availability of adolescent friendly health facilities in the vicinity, facilitates appropriate management of nutrition related health issues.

#### 4. Governmental and Political Level

Due importance should be given to adolescent health at the highest political and governmental level. This in turn helps in framing adolescent friendly policy, rules, regulations and legislations. Increased taxes on junk food, sweetened beverages, alcohol and tobacco would decrease their intake and cheaper fruits and vegetables would increase their consumption. Law against junk food availability like those for tobacco in educational institutions would result in its decreased intake. Making food labels compulsory for all ready to eat items and beverages is another important policy decision. Media messages regarding unhealthy eating and body image should also be regulated. The Government of India's *Rashtriya Kishore Swasthya Karyakaram* launched in 2014 has adolescent nutrition as one of the important focus areas. The various national programs framed toward achieving nutritional sufficiency amongst adolescents are listed below.

##### *National Iron + Initiative*

The guidelines for control of iron deficiency anemia over the entire life-span were published by the Government of India in 2013 and was named as National Iron + Initiative. Evidence based strategies and comprehensive action plans were outlined to eliminate anemia in the target groups comprising of children, adolescents, pregnant and lactating women and all women of reproductive age groups. For school and out of school adolescents, the weekly iron and folic acid supplementation (WIFS) program was initiated. WIFS has the following components:

- Supervised intake of weekly iron (100 mg) and folic acid (500 µg) tablets to all adolescents in school and in *Aganwadis* (for out of school adolescents)
- Biannual intake of albendazole tablet (400 mg)
- Screening of all adolescents for anemia and referral for treatment
- Information and counseling regarding dietary intake, hygiene and prevention of worm infestation.

For pregnant adolescents and women, 100 mg of elemental iron and 50 µg of folic acid are recommended for 100 days each in the antenatal and postnatal period. They are also provided with insect repellent treated bed nets for their personal use. Weekly iron supplementation is given by ASHA workers to all women of reproductive age group (15–45 years).

##### *SABLA Program for Adolescent Girls*

Under the SABLA program, adolescent girls are given a take home ration of fresh prepared food that provides 600 calories with 18–20 g of protein along with micronutrients.

#### Screening and Assessment of Nutritional Status in Adolescents

Apart from an annual screening, adolescents should be screened for their nutritional status at every health visit. Nutritional intake and concerns about body image form an important part of routine psychosocial screening using the HEADSS tool (Chapter 24.3). Food frequency questionnaires, 24 hour dietary recall and food diaries can also be used for a detailed dietary assessment. Physical activity levels, details of current or past weight control behavior and media usage should also be evaluated. Height, weight, BMI and blood pressure should be plotted on appropriate charts. Obesity, hypertension, anemia or undernutrition that are detected on examination require detailed investigations and appropriate management.

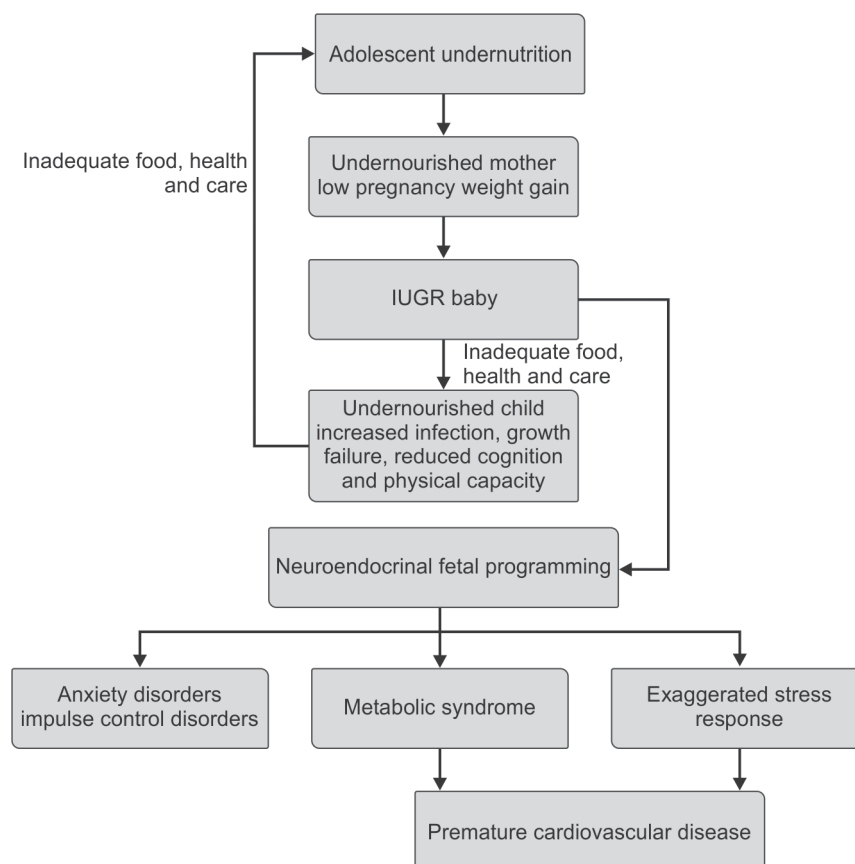

#### ADOLESCENT NUTRITION AND LIFESTYLE DISORDERS

According to WHO, 33% of disease burden and almost 60% of premature deaths among adults can be attributed to causes that begin in adolescence like poor dietary habits, tobacco, alcohol use and risky sexual behavior. Improving adolescent nutrition especially those of girls will play a major role in achieving Millennium Development Goal (MDG) 1 (eradicate extreme poverty and hunger), MDG 4 (reduce child mortality) and MDG 5 (improve maternal health).

Recent research has proven that maternal undernutrition and anemia have not only adverse effects in utero, but also epigenetic effects that can be transmitted from one generation to another. Effect of maternal undernutrition is shown diagrammatically in **Flow chart 1**. These are explained in detail below:

- Maternal undernutrition results in low birth weight babies and premature births. These babies, especially those with intrauterine growth restriction have increased mortality and morbidity. Poverty leads to poor health, inadequate nutrition and poor child care. This in-turn causes childhood undernutrition, inadequate catch up growth, stunting, increased susceptibility to infections and impaired cognition that continues into adolescence and adulthood.
- According to Barker hypothesis and developmental origin of adult health and disease hypothesis, maternal undernutrition and anemia cause fetal neuroendocrine programming. This includes reduced insulin sensitivity and pancreatic beta cell mass, low nephron number, poor muscle mass, altered arterial structure and increased cortisol secretion. There is an up regulation of hypothalamic pituitary axis and sympathetic nervous system leading to in utero susceptibility to develop obesity, hypercholesterolemia, diabetes mellitus and hypertension in later life. When these undernourished babies are exposed to a high caloric energy dense diet in childhood, they put on weight rapidly and develops metabolic syndrome in adulthood.
- Fetal exposure to toxic stress in form of maternal undernutrition has an effect on the brain development by increased exposure to cortisol levels. It alters brain neuronal connectivity, cortical thickness, white matter fiber tracts and size and shape of gray matter structures like amygdala and hippocampus. This results in an exaggerated stress response, poor memory, impaired cognitive ability and predisposes to anxiety and impulse control disorders due to faulty development of the orbitofrontal neural tracts. It also leads to an increase in lifelong susceptibility to coronary artery disease.

As mentioned before in this chapter, overnutrition among adolescents is on the increase. This has led to an increase in metabolic syndrome in adolescence. Metabolic syndrome increases the likelihood of developing stroke and heart attack by two to three times and type 2 diabetes mellitus by five times compared to normal population. Hence, it is very important to identify and manage adolescents who are *at risk* of developing metabolic syndrome. In 2007, the International Diabetes Federation (IDF) published the consensus definition of metabolic syndrome in children and adolescents. Abdominal obesity, clinically determined by measuring the waist circumference at the umbilicus is an essential feature of the definition. The presence of the essential feature plus any two of the other four factors defines the syndrome. The other four factors include hypertriglyceridemia, low HDL, hypertension and impaired fasting glycemia. Early detection, followed by treatment in form of

**Flow chart 1** Effect of adolescent undernutrition on life cycle

lifestyle related intervention and possibly, pharmacotherapy with metformin form an important part of management of metabolic syndrome. Polycystic ovarian syndrome, the most common endocrinopathy seen in female adolescents is also attributed to increased prevalence of obesity and insulin resistance. Obesity has also lead to an increase in type 2 diabetes mellitus and hypertension among adolescents.

According to Diagnostic and Statistical Manual of Mental Disorders (DSM-5), feeding and eating disorders include binge eating, anorexia nervosa, bulimia nervosa, pica, rumination and avoidant/restrictive disorder. Currently, with media's emphasis on equating beauty to thinness, the incidence of eating and feeding disorders are on the rise amongst adolescents. An Indian study published in 2007, estimated the prevalence of eating disorders in adolescents as 1.25%. A 2012 survey from Bengaluru revealed that Indian psychiatrists have noted a recent increase in clinical cases of eating disorders. Anorexia is characterized by failure to maintain a minimal normal weight along with intense fear of gaining body weight and distorted body image. Bulimia is characterized by recurrent episodes of binge eating and purging behavior in the form of emesis or use of laxatives. Both these psychiatric disorders are discussed in detail in Section 21.

Optimal and adequate adolescent nutrition determines health of a nation. All stakeholders including government, community leaders, educational institutions, health care professionals, parents and adolescents themselves have a major role to play in ensuring appropriate adolescent nutrition at all levels of health care.

### IN A NUTSHELL

1. Adolescence is a nutritionally vulnerable period.
2. Adequate nutrition and physical activity in adolescence are essential for current, future and intergenerational health.
3. India is facing the double jeopardy of adolescent undernutrition and overnutrition. Lifestyle disorders are on the increase.
4. Micronutrient deficiencies are common in Indian adolescents.
5. Adolescent nutrition is determined by multiple socio-ecological factors.
6. Nutritional status of adolescents must be assessed at every health visit.
7. Girls are especially vulnerable to nutritional deficiencies.
8. Nutritional well-being has to be ensured over the entire life span to break the intergenerational cycle of undernutrition and poor health.

## Chapter 25.3

# Mental Health

Priya Mary Mammen

Mental health is defined as the *successful performance of mental function, resulting in productive activities, fulfilling relationships with other people, and the ability to change and to cope with adversity*. Poor mental health is not synonymous with mental illness. Mental disorders refer to conditions that are characterized by alterations in thinking, mood, or behavior associated with distress and/or impaired functioning. Global estimates of the prevalence of psychiatric disorders in adolescence have reported that almost one in five adolescents has a diagnosable psychiatric disorder and about 10% of these have severe disturbances. In India it is documented that the prevalence of psychiatric disorders among adolescents under 16 years is 12.5%. In addition, almost half of the mental illnesses diagnosed in adults have their onset in the adolescent period and those with onset in childhood are invariably found to persist into adolescence. Mental health issues in adolescents have far reaching effects in their development, leading to a host of other problems which affect the individual, family and society at large. This chapter will deal with poor mental health (e.g., peer pressure, bullying and stress) and few specific disorders seen in adolescents.

### DETERMINANTS OF MENTAL HEALTH IN ADOLESCENTS

Three main determinants have been identified: *Individual attributes, social circumstances and environmental factors*. These three determinants can act and interact as adverse factors which pose a risk to mental wellbeing, or as protective factors which enhance positive mental health. There are many factors which adversely affect the mental health of an adolescent; some of these have been enumerated below.

#### 1. Peer Pressure

Eric Erikson's theory on psychosexual development mentions adolescence to be the stage of identity versus role diffusion. An adolescent is in a struggle to develop an ego identity and group identity. Adolescence is a period when individuals spend considerable time with peers as compared to their families. Peer influence can have both positive and negative effects. These effects have been already discussed in the Chapter 25.1 on factors influencing the adolescent health. Adolescents who usually conform to the norms of their peer group are usually better accepted socially. Rejection by peers has been found to have higher associations with school drop outs, delinquency and substance use. However, peer group values can often be in conflict with one's internalized value systems. The pressure on the adolescent to be socially accepted by conforming to the peer group norms and peer pressure, can at times give rise to significant problems. Peer pressure has been found to have the maximum influence in early and middle adolescence. Peer pressure can occur either through direct influence, modeling or by perceived norms. Adolescents who are most vulnerable to the effects of peer pressure are those with low self-esteem, under assertive traits, have family backgrounds which are disturbed or parents who are uninvolved. Peer pressures can be spoken or unspoken—spoken peer pressures are those where friends directly tell an adolescent what to do while the unspoken pressures are those that the adolescent observes in their peer and wishes to imitate.

#### Substance Abuse

A large number of individuals, who go on to develop substance use disorders, have a history of initiating substance use in their adolescence. It has been found that one of the strongest predictors of alcohol and tobacco use in teenage years has been social motivation. Studies done across India, have reported that peer pressure has been one of the most commonly cited reasons for initiating substances like alcohol, tobacco and inhalant substance use in 35–45% of adolescents. Peer pressure has been found to have a stronger influence on adolescent substance use, than the presence of substance use disorder in a parent or sibling.

#### Sexuality

Adolescence is a period of sexual maturation and developing a sexual identity. Sexual peer norms, peer sexual behavior and peer pressure to have sex have been strongly associated with premarital sex in adolescence. Peer pressure is especially significant in adolescents who report poor quality of parental relationship with parental inhibition in discussing these issues with their child.

#### Body Dissatisfaction

With hormonal influences and bodily changes that occur in this stage, an adolescent is understandably preoccupied with appearance. It is therefore not surprising that disorders like anorexia nervosa and bulimia usually have their onset in this age group. Many studies have shown however, that *appearance-related social pressure* from peers is one of the most crucial factors for body image concerns in both adolescent boys and girls. Peer interactions and comparisons for thinness have been associated with weight concerns and dieting in adolescent girls, while peer comparisons for physical stature and musculature have been reported as significant for body dissatisfaction in adolescent boys.

#### Other Risk Taking Behaviors

Coercive behaviors and reinforcement of these by peer groups have been associated with high risk behavior in adolescents. Truancy from school, vandalism, traffic offences and weapon use are commonly associated with peer group influence.

Peer influence plays a major role in one's development especially in vulnerable individuals. It is therefore recommended that preventive interventions need to address peer pressure influence through social and life skills training programs.

#### 2. Bullying

Bullying is defined as *an intentional and repetitive aggressive behavior from one person that causes harm to a vulnerable peer*. The definition of bullying implies certain characteristics namely: a hostile intent, causes distress to the victim, implies a power imbalance between the bully and the victim and tends to be repetitive. There are various forms of bullying: physical, verbal and social aggressive/relational. While physical and verbal types are more direct forms of bullying, social aggressive in the way of gossip, rumor circulation and being ostracized from peer groups, is an indirect form. Physical (hitting, kicking) and verbal (teasing, name-calling) aggression is commonly described in male adolescent bullies; female adolescent bullies tend to resort to more socially aggressive bullying tactics. Over the past few years with the advent of social media platforms, classic forms of bullying have been replaced by newer forms like cyberbullying.

#### Prevalence

Bullying has been widely reported across the world, however prevalence rates are varied across countries. Prevalence studies of bullying in school populations have reported low rates of 5%

in some Scandinavian countries to higher rates of 13–24% in USA and England. Few studies which have looked at the prevalence rates in Asian countries like India and Taiwan, have reported much higher rates like 50–60%. These reports also state that male adolescents bully more than females especially with regard to physical aggression. There also appears to be a reducing trend in the prevalence of bullying by late adolescence. Three groups of individuals who are involved in bullying have been identified, namely bullies (perpetrators), victims and bully-victims (both perpetrator and victim).

### *Risk Factors in Victims*

While bullying has been reported as a universal phenomenon, the risk factors for the same are multifactorial. Important risk-factors at individual, family, school and community level are listed below:

1. *Individual factors* Low self-esteem, poor social skills, physical and intellectual disability, aggressiveness.
2. *Family factors* Domestic abuse, authoritarian parenting, inadequate parental supervision, broken homes.
3. *School factors* Overcrowding, socioeconomic disparities, inadequate teacher supervision, aggressive peers.
4. *Community factors* High crime areas, overcrowding, lower socioeconomic status.

### *Outcome of Bullying*

All three groups directly involved in bullying develop mental health concerns. Both internalizing and externalizing disorders are reported in victims of bullying. *Internalizing disorders* like anxiety, depression, post-traumatic stress disorder and suicide are more prevalent. Cross-sectional studies on bullies have found higher rates of *externalizing disorders* like conduct disorder and attention deficit hyperactivity disorder, delinquency, substance abuse, interpersonal difficulties and school failure. While the bully-victim is the least prevalent among the three groups, they have the highest levels of psychopathology, with both externalizing and internalizing disorders. Numerous studies that have looked at the effects of bullying have emphasized the need to address this issue in preventive programs.

### *Interventions*

Antibullying programs have been initiated in schools. One of the earliest structured programs was the Olweus Bullying Prevention Program (OBPP) which was introduced in schools across Sweden and Norway and the KiVa which was initiated in Finland. The program was geared toward the 5–15 year age group and had interventions addressing the problem at an individual, parent and school administrative level. Controlled trials of these preventive intervention programs have found decrease in self and peer reported bullying. A systematic review which looked at the effectiveness of antibullying interventions, found an overall reduction of 20–23% in bullying across schools where these were implemented. These programs have not yet been implemented in India.

## **3. Stress**

Stress is defined as a *state of mental or emotional strain resulting from adverse or demanding circumstances*. While stress can affect mental health, low levels of stress have been found to have beneficial effects and are associated with better performance. Stressors can be acute or chronic. Acute stress is usually characterized by sudden onset, is more severe, but time limited. Many life events fall in this category. In contrast, chronic stress occurs over a longer duration of time, is generally less severe and gradual in onset. However, both types of stress are known to affect adolescent mental health, though correlates may differ. While almost every adolescent

undergoes stress in some form or the other, not all of them develop mental health concerns. This brings into light the mediating effect of resilience and coping in the context of adversity. Resilience can be determined by both internal factors such as high intellect, good self-esteem and problem based coping styles, and external factors like strong social support, involved/supportive parents and peers. Therefore, interactional effects of the stressor and an adolescent's resilience will determine the perception of the stress and its effect on mental health. Studies that have looked at perceived stress have found gender differences, with higher prevalence in girls. Adolescence has been reported as the most vulnerable period for stress to affect functioning, as compared to early childhood, or in adults.

### *Common Stressors in Adolescents*

School/academic pressure; relationship issues; peer pressure and bullying; more responsibilities; future career and financial concerns; and chronic physical illnesses, family conflict, sexual or physical abuse.

### *Associations Between Perceived Stress and Mental Health Issues*

Higher levels of perceived stress in adolescents have been linked to nonspecific health concerns like physical complaints, fatigue and sleep disturbances, to more specific disorders like anxiety, depression and post-traumatic stress disorder (PTSD). While acute, sudden and intense trauma has been associated with PTSD and anxiety disorders, chronic adversity has been commonly linked to later development of depression and personality problems. However as mentioned, individual vulnerabilities interacting with negative life events would finally determine these outcomes.

## **MENTAL HEALTH PROBLEMS IN ADOLESCENCE**

World Health Organization has identified specific disorders which are commonly seen and can be managed in primary care pediatric settings based on the findings of epidemiological studies on the prevalence of psychiatric disorders in adolescents. Among these, depression, anxiety, substance use and behavior disorders are the most prevalent. We have already discussed anxiety and conduct disorders in Section 21. Others are detailed below.

### **Depression**

Depressive disorders are the most common psychiatric disorders seen in adolescents. While historically reactive and endogenous types of depression have been described, current classificatory systems have classified these under major depressive disorders (MDD) and adjustment disorders respectively. Adjustment disorders with transient and mild depressive symptoms which are temporally correlated with a recent stress are highly prevalent in adolescents and usually require only brief nonpharmacological interventions. MDD however needs to be diagnosed and treated appropriately. The diagnostic criteria for MDD are given in **Box 1**. There are several other subtypes of MDD which are out of the scope of this discussion.

### *Epidemiology*

Global community studies on depression have reported prevalence rates ranging from 0.2% to 17%, with a median prevalence of 4% in the adolescent age group. While pre and early adolescent MDD rates are similar in both genders, a female preponderance is noted following puberty, with M:F ratio of 1:2. A significant proportion of adolescent youth with MDD have comorbid anxiety disorders (30–40%), conduct disorders (15–30%) and substance use disorders.

**BOX 1 ICD-10 Diagnostic criteria for major depressive disorder**

- A. Depressive symptoms lasting at least 2 weeks
- B. At least two of the following three symptoms:
  1. Depressed mood present most of the day
  2. Loss of interest in pleasurable activities
  3. Decreased energy
- C. Additional symptoms (four or more):
  1. Decreased self esteem
  2. Excessive guilt
  3. Suicidal thoughts or behavior
  4. Decreased concentration
  5. Psychomotor agitation or retardation
  6. Sleep disturbance
  7. Change in appetite and weight

**Etiology**

A combination of genetic vulnerability and environmental factors has been implicated in the etiology of depression. Having a parent with depressive disorder has been associated with a two times higher chance of developing an MDD. One of the most cited biological theories regarding depression have reported low levels of monoamines and serotonin in individuals with MDD.

**Clinical Features**

Clinical symptoms encompass groups of cognitive, affective, biological and behavioral symptoms which are characteristically seen in depression and are listed below:

- *Cognitive* Cognitive triad of helplessness, hopelessness and worthlessness; guilt and suicidal ideation
- *Affective* Low or irritable mood
- *Biological* Changes in sleep, appetite and libido
- *Behavioral* Suicidal behavior, crying spells, psychomotor retardation/agitation.

**Assessment**

Common medical conditions which may present with depressive symptoms need to be ruled out. This would include hemoglobin, leukocyte counts, ESR, thyroid function tests and creatinine. Psychological assessments in the form of rating scales to rate the severity of depression at baseline and for monitoring can be administered. Some of the common rating scales used are the Beck Depression Inventory (BDI), the Childhood Depression Rating Scale (CDRS) and the Hamilton Depression Rating Scale (HDRS).

**Management**

Treating an adolescent with depression will need to take the following factors into consideration:

- *Severity of episode* May require inpatient admission in case of severe psychomotor retardation, suicide risk or catatonic symptoms.
- *Presence of psychotic symptoms* Will require initiation of an antipsychotic medication along with the antidepressant, which will need to be continued through the acute phase of treatment and then tapered.
- *Presence of past hypomanic/manic episodes* Will require antidepressants under the cover of a mood stabilizer at adequate therapeutic dose, to prevent the likelihood of a switch.
- *Presence of recurrent depressive episodes* Will require prophylactic antidepressant treatment (continuation of medications for 2–5 years).

**Nonpharmacological treatment** Nonpharmacological treatments have been recommended as first line treatment in mild and moderate depressive episodes. Cognitive-behavior therapy (CBT),

interpersonal therapy (IPT), psychodynamic therapy and family based therapies have been used; the evidence is most in favor of CBT and IPT in adolescent depression.

**Pharmacological treatment** Various classes of antidepressants can be used, however most guidelines recommend Serotonin Specific Reuptake Inhibitors (SSRIs) as the first line medications. These medications are easily available, have easy dosing schedules and relatively better side effect profiles and are therefore easy to prescribe at a primary care pediatric setting. Common SSRIs and their dosing schedules are described in **Table 1**.

Tricyclic antidepressants can be used as second line medications. However, are not usually prescribed in view of their side effect profile. For the first episode of depression, the treatment is divided into two phases: an acute phase lasting for 2–3 months and a continuation phase lasting for 6 months after the acute phase of treatment. The antidepressant needs to be continued through the two phases of treatment and is usually maintained at the dose required for acute control. While the above treatment regimens are recommended at primary care levels, it is recommended that more severe forms of depression with psychotic, catatonic, high suicide risk, bipolar or recurrence features, be referred to tertiary centers for further management.

**Substance Abuse**

The use of psychoactive substances by adolescents is a universal phenomenon. Substance use has been considered by the United States Substance Abuse and Mental Health Services Administration as *minimal or experimental use* with minimal consequences and *substance abuse* as regular with more severe and serious consequences. Both the International Statistical Classification of Diseases and Related Health Problems (ICD-10) and the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) have defined criteria for substance abuse and dependence, with current revisions further made in the DSM-5. The ICD-10 classifies substance use disorders into acute intoxication, harmful use, dependence syndrome, withdrawal states, psychotic states and amnesic syndrome. While substance use and acute intoxication are highly prevalent in adolescents, substance abuse and dependence in this age group is relatively uncommon. The features of substance abuse/harmful use and substance dependence as mentioned in the ICD-10 are listed below.

**Substance Abuse/Harmful Use**

A pattern of substance use that is causing damage to physical and mental health without other features are suggestive of dependence. The term *abuse* has been similarly used in the DSM-IV, which also includes the social, legal and occupational consequences of this pattern of substance use.

**Substance Dependence**

A cluster of physiological, behavioral and cognitive phenomena characterized by three or more of the following over a one year period—tolerance, physiological withdrawal, inability to control, preoccupation with substance use, continued use in spite of harmful consequences and craving.

**Table 1** Dose and dosing for the common serotonin specific reuptake inhibitors

Drug	Dose/day
Fluoxetine	20–40 mg od
Citalopram	20–40 mg od
Escitalopram	10–20 mg od
Sertraline	50–100 mg od

Most adolescent substance use is usually experimental (more out of curiosity) or recreational (during social gatherings).

### Epidemiology

Prevalence rates of substance use in adolescents vary widely with extremely high rates of 50–75% for alcohol reported in the UK and 40–42% of illicit drug use in the UK and USA. Prevalence estimates of substance abuse and dependence however have ranged from 3.3% to 9.8% in 17–19 year olds in western studies. Global trends show that alcohol and nicotine are the most commonly used substances among adolescents. Among illicit drugs, cannabis and opiates are the most frequently abused, followed by cocaine and amphetamine. One of the largest national studies done in India, 'National Survey on Extent, Pattern and Trend of Drug abuse in India' was sponsored by the Ministry of Social Justice and Empowerment, Government of India (MSJE, GOI) and the United Nations Office on Drugs and Crime, Regional Office for South Asia (UNODC, ROSA). The results of this survey published in 2004, reported that the most prevalent substance of abuse was alcohol (21.4%) and tobacco, followed by cannabis (3%) and heroin (0.2%). While the population prevalence for opiate use was low, higher prevalence of opiate use was seen in treatment clinics. The highest prevalence of substance use was seen in the northeast region. Most of the individuals with substance use disorders also reported associated high risk behaviors like sharing of needles or unsafe sex practices.

### Risk Factors for Substance Use

Risk and protective factors have been identified in substance use disorders. The most common risk factors are listed here:

- **Genetic factors** Family history of substance use or mood disorder in 1st or 2nd degree relatives
- **Environmental factors** Substance abusing peers, cultural and religious sanction for substance use, easy availability of drugs, media influence, poverty
- **Individual factors** Psychiatric disorders like conduct disorder, depression and ADHD, traits of impulsivity, aggression and risk-taking, low self-esteem, low intelligence
- **Family factors** Family conflict, poor parental supervision, drug abusing parent, child abuse, permissive or authoritarian parenting.

### Assessment

It is important to identify an adolescent with substance use early on and make an assessment of the pattern of substance use before planning intervention strategies. There are screening questionnaires which have been used to identify substance use disorders. One of the common used screening measures, recommended by the American Academy of Pediatrics committee for substance use in adolescents is the CRAFFT which is a mnemonic acronym of 6 questions (**Box 2**). A few other screening measures for use in adolescents are the Adolescent Drinking Index (ADI), Drug Use Screening Inventory Revised (DUSI-R) and the Teen Addiction Severity Index (T-ASI).

#### BOX 2 Items of the screening questionnaire for substance use

##### The CRAFFT questionnaire

- C – Have you ever ridden in a *car* driven by someone (including yourself) who was *high* or had been using alcohol or drugs?
- R – Do you ever use alcohol or drugs to *relax*, feel better about yourself, or fit in?
- A – Do you ever use alcohol/drugs while you are by yourself, *alone*?
- F – Do you ever *forget* things you did while using alcohol or drugs?
- F – Does your family or *friends* ever tell you that you should cut down on your drinking or drug use?
- T – Have you gotten into *trouble* while you were using alcohol or drugs?

### Interventions

A complete physical and mental status examination is needed to look for signs of intoxication, withdrawal or physical and psychiatric comorbidities or sequelae of the substance use. Most adolescents with substance use disorders which are not of a dependent pattern will require the following interventions:

- **Psychoeducation** The harmful effects of substance use and the associated consequences are enumerated
- **Motivation enhancement therapy** An adolescent's perception of the advantages and disadvantages of substance use are assessed and challenged using motivational interviewing techniques.
- **Family and community based interventions** Parent based therapies which focus on improving parent-adolescent relationship; addressing better parenting styles and conflict resolution are implemented. Multisystemic therapy models which target family, school and peer functioning have been found to be effective.
- **Assertiveness training** Learning to be assertive in situations where peer pressure has contributed to substance use.
- **Assessment and management of comorbid psychiatric conditions** like conduct disorder, depression or ADHD.

Adolescents who have a pattern suggestive of dependence will most often require inpatient care with detoxification and de-addiction strategies specific to the substance being abused.

### Preventive Interventions

Substance use in adolescents has been associated with other high risk behaviors and has incalculable costs in the form of morbidity and mortality, academic underachievement, family dysfunction, legal consequences and economic implications. Preventive interventions are therefore needed to address this complex issue. Highly intensive programs are recommended for adolescents at risk. Many school based programs have started intervening at the primary school level. Most preventive programs consist of psychoeducation on drug use listing its consequences, life skills education addressing problem solving, assertiveness and handling peer pressure, self-esteem enhancement, managing leisure and other forms of recreation, and education on high risk behaviors.

### Personality Disorders

Personality disorders (PD) generally refer to an enduring and persisting pattern of maladaptive behavior, usually implicated as being consistent over time, place and circumstance. As childhood and adolescence are invariably considered as a stage of constant developmental change, the concept of stability of personality cannot be considered here. Personality disorders are by and large therefore conceptually not diagnosed below 18 years of age.

Both the ICD-10 and the DSM classificatory systems have listed various types of personality disorders which are mentioned in **Table 2**. Personality disorders in both the ICD-10 and DSM IV-TR classifications had used a categorical approach to classifying these disorders. The DSM-5 has been modified to include both a categorical and dimensional approach in diagnosing personality disorders but the categories essentially remain the same.

Child and adolescent approaches to the development of personality have addressed the theories of temperament and attachment in early childhood, to the constellation of personality traits in adolescence. While personality disorders are therefore not diagnosed, early childhood and adolescent traits in these domains and their association with the later development of personality disorders have been described. Certain disorders diagnosed in children and adolescents like conduct disorder, have been suggested as *prodromal personality disorders* in view of their continuum with adult antisocial personality disorder. Personality development is ultimately an interaction between genetic and environmental influences and the development of a disorder is

**Table 2** Summary of the personality disorders in ICD-10 and DSM-5 classificatory systems

DSM-5	ICD-10
1. Paranoid	Paranoid
2. Schizoid	Schizoid
3. Antisocial	Dissocial
4. Borderline	Emotionally unstable
5. Histrionic	Histrionic
6. Obsessive-compulsive	Anankastic
7. Avoidant	Anxious/avoidant
8. Dependent	Dependent
9. Narcissistic	-
10. Schizotypal	-

invariably related to the quality of these interactional processes. Maladaptive ways of interpreting situations and people can have both a biological influence (e.g., in disorders like autism) and an environmental influence (e.g., a life event like abuse).

### Childhood Predictors of Development of Personality Disorders in Adulthood

- **Early temperamental traits** Impulsivity, behavioral disinhibition, low frustration tolerance associated with antisocial and borderline PDs.
- **Attachment problems** Disorganized attachment patterns linked to borderline PD.
- **Childhood psychopathology** Disruptive behavior disorders linked to antisocial PD; anxiety disorder linked to paranoid, histrionic and obsessive compulsive PD.
- **Personality traits in adolescence** Paranoid, borderline and narcissistic traits linked to antisocial behavior in adulthood.
- **Environmental factors** Physical, sexual, verbal abuse and neglect in early childhood, low socioeconomic status.
- **Family factors** Single parent families, death of parent, family conflict.
- **Parenting factors** Parental psychopathology, parent substance abuse and criminal behavior, maternal over control or lack of closeness to parent.

### Delinquency

The term *delinquent* typically refers to a juvenile (a person below 18 years of age) who has committed an act which would be considered a criminal offence. While the term delinquency seems synonymous with crime and the legal system, it is important to remember that *delinquent acts* are quite commonly seen in adolescents. Adolescence is a period of accomplishing the task of autonomy versus dependency. In the process of establishing their self-identity, adolescents can often become rebellious and commit delinquent acts. Delinquency therefore needs to be considered in the context of its frequency, severity and persistence in an adolescent. While studies have shown that about 60–80% of adolescents may have engaged in some sort of juvenile offence, most of these offences are nonviolent or status offences which may have occurred infrequently and only during the adolescent period. However, delinquent acts can also be violent in the form of weapon use, physical aggression, homicide, arson and sexual offences.

### Epidemiology

While prevalence rates of delinquent acts in youth have been documented in other countries, the same in India have not been clearly studied. It has however been seen that when compared to the high prevalence of the behavior, only a small number have been violent offences (approximately 10%), with a higher prevalence of these being in male adolescents. Western studies

have shown higher prevalence in certain noncaucasian youth and ethnic minorities. Most of the reports on delinquency have found peak incidences in late adolescence.

### Risk Factors

Multiple risk factors have been implicated in the development of antisocial behaviors at individual, family and community levels. While numerous socioeconomic variables have been identified with implications for policy initiatives, there is also a higher prevalence of psychiatric disorders which have been associated with delinquency.

These include conduct disorders, ADHD, learning disability and substance abuse. While other psychiatric disorders like mood disorder and psychosis have been identified in delinquency, their overall prevalence is low compared to the disorders listed above. Other risk factors identified include lower socioeconomic status, high crime neighborhoods, male gender, negative life events/childhood trauma, poor social support, poor parental supervision and domestic violence.

### Interventions

Ideal interventions for delinquency should be able to address the issue at primary, secondary and tertiary levels of care.

- **Primary level** Interventions at the primary level would be those that would reduce the incidence of delinquent behavior in those who had not yet developed it. Most primary level interventions would therefore involve policy initiatives addressing social risk factors, parenting based training programs and school based programs involved with life skills training.
- **Secondary level** Intervening with adolescents who have started getting into delinquent patterns of behavior through school and parent based programs. Most of the evidence for these is from multisystemic interventions at individual, family and community levels.
- **Tertiary level** Interventions at this stage address juveniles who have been convicted by the legal system. The primary legal framework for juvenile justice in India is the Juvenile Justice Act 2000, which addresses the prevention and treatment of juvenile delinquency and also provides guidelines for the protection and rehabilitation of children who are under the juvenile justice system.

Mental health is an often neglected area of adolescent health. According to a recent UNICEF report, nine out of ten of the 1.2 billion adolescents in the world live in developing countries and 20% are from India. While there are many factors which affect the mental health of adolescents, these need to be addressed through preventive interventions in a large way in developing countries in order to reduce the overall morbidity and mortality associated with disorders which can subsequently develop.

### IN A NUTSHELL

1. Mental health is defined as the successful performance of mental function, resulting in productive activities, fulfilling relationships with other people, and the ability to change and to cope with adversity.
2. *There are 3 main determinants of mental health* Individual attributes, social circumstances and environmental factors. These three determinants can act and interact as adverse factors or as protective factors.
3. Adolescent mental well-being is affected by peer pressure, bullying, and stress.
4. Major mental health problems in adolescents include depression, anxiety, substance abuse and behavior disorders.
5. Mental health problems need to be addressed through preventive interventions to reduce the overall morbidity of these problems in adolescents.

## Chapter 25.4

# Injuries, Violence and Suicide

Srikanta Basu

Every year, millions of children all over the world die from preventable causes. Injuries and violence are responsible for a large majority of these causes. Causing more than five million deaths every year, violence and injuries account for 9% of global mortality and as many deaths as HIV, malaria, and tuberculosis combined. Young people are among the most vulnerable. Injury death rates are significantly higher in low and middle-income countries, which already account for more than 95% of the world's deaths from injuries and violence.

### IMPACT OF INJURIES

Worldwide, eight of the fifteen leading causes of death for people aged 15–29 years are injury related, including road traffic injuries, suicides, homicides, drowning, burns, war injuries, poisonings, and falls (**Table 1**). According to findings of 2010 Global Burden of Disease Study, injuries cost the global population some 300 million years of healthy life every year, causing 11% of disability-adjusted life years (DALYs) worldwide. Road-traffic crashes were the number one killer of young people and accounted for nearly a one-third of the world injury burden—a total of 76 million DALYs in 2010, up from 57 million in 1990.

**Table 1** Leading causes of death in children, both sexes, World, 2004

Rank	10–14 years	14–19 years
1.	Lower respiratory infections	Road traffic injuries
2.	Road traffic injuries	Self-inflicted injuries
3.	Drowning	Violence
4.	Malaria	Lower respiratory infections
5.	Meningitis	Drowning
6.	HIV/AIDS	Tuberculosis
7.	Tuberculosis	Fire-related injuries
8.	Diarrheal diseases	HIV/AIDS
9.	Protein-energy malnutrition	Leukemia
10.	Self-inflicted injuries	Meningitis

Source: WHO (2008), Global Burden of Disease: 2004 update.

Apart from the high death toll, injuries during childhood and adolescence are also associated with high morbidity—for every injured child who dies, several thousand more survive with varying degrees of disability. The impact on the society is tremendous—everyday, thousands of families are robbed of their children and thousands of children have to learn to cope with the consequences of their injury, which, in some cases, can be both long-lasting and profound.

### UNDERSTANDING INJURIES

#### Definitions

Injuries have traditionally been regarded as unavoidable *accidents*. Accident is defined as an unintended, unplanned event, independent of human will power. Whereas, injury may happen out of unintentional or intentional harm and is a degree predictable and largely preventable. Injuries are defined as *acute exposure to physical agents such as mechanical energy, heat, electricity, chemicals, and nonionizing radiation interacting with the body*

*in amount or rates that exceed the threshold of human tolerance*. Injuries are broadly classified into two types—as intentional (deliberately inflicted) or unintentional injuries (**Box 1**).

#### BOX 1 Classification of injuries

##### I. Intentional injuries

- Self-inflicted injuries (suicide)
- Interpersonal violence (homicide, sexual, child abuse)
- Collective violence (war)
- Other intentional injuries (legal intervention)

##### II. Unintentional injuries

- Road traffic injuries
- Drowning
- Poisoning
- Falls
- Burns
- Other unintentional injuries (firearm injuries)

### Setting of Injuries

Both intentional and unintentional injuries can also be categorized according to the place where they occurred, i.e., on the road, at home, at a leisure/sport facility, at school or in the workplace, or according to the circumstances in which they occurred, e.g., during working hours (occupational injury) or during leisure time.

### Indian Scenario

Injuries account for 9–10% of total mortality in India. The common causes of unnatural accidental deaths are—road traffic injuries (37.2%), poisoning (7.8%), drowning (7.8%), railway accidents and rail-road accidents (7.7%), and fire related deaths (6.8%). Age-wise, 6.9% of such victims were up to 14 years of age. There are hardly any published data on injuries and violence in the age group 10–19 years in India.

### Etiology

#### Why are Adolescents at Risk from Injuries?

Overall rates of injury and death increase dramatically from childhood to late adolescence. Due to developmental and social factors, such as time spent without adult supervision and increasing independence, adolescents are more likely to engage in risk-taking behaviors than either younger children or adults.

*Developmentally*, research over the past decade has found that parts of the frontal lobe, in particular, the prefrontal cortex which governs judgment, decision-making, reasoning and impulse control—appears not to fully mature until the age of 20 or 25 years making adolescents more likely to engage in risk-taking behaviors.

#### Risk-taking Behavior

Nearly 50% of the morbidity and mortality in adolescents stems from four behaviors: sexual activity, substance use and abuse, motor vehicle use, and interpersonal violence. These behaviors have their origin in adolescence, and is common among all age, socioeconomic and ethnic groups. All of these behaviors have a probability for negative outcome and share one common thread, i.e., risk taking tendency of the adolescents. Moreover, these behaviors continue in adult life and are responsible for some of the major causes of morbidity and mortality and are largely preventable. While young children may inadvertently take risks because they lack appropriate skills to do otherwise, older children and adolescents may actively seek out risk. Risk-taking behavior may allow adolescents to feel a sense of control over their lives or else to oppose authority. Research shows that there are high

levels of sensation-seeking behavior among young adults and that there exists a need to maintain a heightened level of physiological arousal. Young people consequently seek new situations and experiences to maintain this level, irrespective of the risks inherent in the experience.

Such sensation-seeking frequently focuses on risky behaviors, while driving a vehicle or crossing a road. Sensation-seeking has been shown to rise between the ages 9 years and 14 years, peaking in late adolescence or in early adulthood, and declining steadily with age. Risk-seeking behavior is a significant predictor of involvement in road traffic injury among child pedestrians as it is for young adolescent drivers aged 16–17 years. Across all ages and particularly among the young, sensation-seeking is more common among boys than among girls. Boys as young as 11 years have a greater affinity for speed, risk-taking and competitive behavior, all of which place them at an increased risk of road traffic injury. But it is also pertinent to remember that though injuries are a frequent and sometimes devastating outcome of risk taking, risks are also inherent in the environment in which adolescents live, work and play.

### Peer Influence

As young children become adolescents, they begin to discover and assert their independence. For many young people, peers are of significant importance and can be the primary source of the social norms with which they strive to conform. Social norms, including peer pressure and the emphasis placed on rebellion in the culture of young people, can affect the manner in which young people drive a vehicle. Research has shown that young drivers experience higher peer pressure than older drivers to commit traffic violations such as speeding, driving under the influence of alcohol and dangerous overtaking.

### Gender

Most studies show a strong male bias, with the male-to-female ratio ranging between 3:1 and 5:1. This relationship holds true across different regions of the world and applies to fatal and nonfatal injuries.

### Road Traffic Injuries

Speeding, drunk-driving, nonusage or improper usage of helmets, seat-belts and child restraints are the five most important risk factors that is consistently associated with fatalities and are largely preventable. An examination of the factors that contribute to injuries reveal that alcohol may be the single most important factor. Drinking and driving increases the risk of being involved in a crash, as well as the severity of resulting injuries. Driving may be impaired at very low levels of alcohol consumption, with the risk of crash involvement growing rapidly, as consumption increases. The effects of alcohol impairment are magnified when combined with fatigue. The other factors which might affect safe driving are consumption of other intoxicants, sleep deprivation, use of mobile or other gadgets. Use of mobile telephones while driving, increases the risk of crash four-fold. The risk is similar for both the hand held and hands free mobile set. Other factors, that may divert the attention of adolescents and have the potential to impact the safe driving texting, in-vehicle internet use, and on-board navigation systems. Two wheeler drivers (motorcyclists and bicycle drivers) are at increased risk of severe head injuries resulting from traffic injuries. Motorcyclists comprise a one-third of all road traffic deaths in the South-East Asia. Head and neck injuries are the main cause of severe injury, disability and death among motorcycle users.

The high incidence of adolescent traffic-related injury is due in part to lack of experience and lack of maturity. The fatal crash rate per km driven for 16–19-years-old is three times the risk for older drivers (age 60+), and fatal crash risk is highest at age 16. Crash

risk for both males and females is particularly high during the first months of driving and drops as young drivers accumulate more experience behind the wheel. One has to understand that many years of experience may be needed for adolescents to become proficient in driving. For example, young drivers may also lack experience to recognize, assess, and respond to the situation or hazards. They may be willing to accept higher levels of risks while walking, riding a bike, or driving a car or motorcycle. These risks may be fueled by emotions, peer pressure, and other adolescent stressors. These problems are further compounded by adolescent alcohol use.

### Drowning

Drowning is the process of experiencing respiratory impairment from unintentional submersion/immersion in liquid. Apart from mortality it may also result in nonfatal injury which may lead to brain damage and long term disability. Around 96% of unintentional drowning deaths take place in low- and middle-income countries. China and India have particularly high drowning mortality rates and together contribute 43% of the world's drowning deaths and 41% of the total global DALYs lost related to drowning. In India, the drowning deaths could be due to boat capsizing, swimming, recreational (during picnics and other outing). Males are especially at risk of drowning, with twice the overall mortality rate of females. Studies suggest that the higher drowning rates among males are due to increased exposure to water and riskier behavior such as swimming alone, drinking alcohol before swimming alone and boating. Increased access to water is another risk factor for drowning.

### PREVENTION OF INJURIES

The traditional model of injury prevention and control rests on managing three Es: *enforcement, education and engineering*. Multipronged strategies are required to control injuries and these strategies complement each other thereby amplifying the final effect. It involves changing the environment, individual behavior, products, social norms, legislation, policy, and ecology related to injury. Broadly it can involve several approaches.

#### Structural Strategies

Involve product modifications (such as machinery guards) and environmental changes (such as adding lifeguarding to pools and recreational water bodies, and building bike lanes, pool fencing) often afford the greatest protection to the population. *But the adolescent's individual choices and behaviors can often override these protections and in the end they do not have a desirable effect.* Moreover, these measures are costly or may not be feasible to implement.

#### Behavioral Approaches

Injury prevention education is the process of changing people's health directed behavior to reduce unintentional injuries. It is a very important component of the effective structural, automatic, environmental, or engineering protections. Effective injury prevention always involves both behavioral (active) and environmental (passive) countermeasures—it is never an either/or proposition. However, behavior education has its limitation as it is difficult to bring about a desired change and the successful outcome is difficult to measure.

#### Legislation and Policy Approaches

Although adolescent behaviors can be changed by introducing a law or policy that mandates compliance—such as requiring protection when operating industrial machinery or requiring helmet use—legislation must be *supported by the public and enforced by local authorities*. Enforcement of legislation indicates state awareness of

the importance and urgency of problem. However in LMICs, laws around the injuries are inadequate and rarely proactive. Other policy approaches that have proven effective for preventing motor vehicle injuries among adolescents as well as other drivers include primary seat belt use laws (where one can be cited for nonuse as a primary offense), enhanced police enforcement, blood alcohol level laws, minimum legal drinking age 21 laws, sobriety checkpoints, and zero tolerance laws for young and inexperienced drivers. Policy changes that discourage early adolescent driving, such as rising insurance costs, expensive driving schools, and GDL laws, have already reduced the proportion of 16-year-olds who hold a driver's license from nearly 43.8% in 1998 to 29.8% in 2006 in US.

### Ecological Approaches

The most effective injury prevention efforts are structured within an ecological framework, focusing on individual modifiable factors, family, peer group, work site, and community and sociocultural factors simultaneously. For example, legislation requiring bicycle helmet use should be accompanied by an educational campaign for children and parents, police enforcement in the community and discounted sales of helmets by local merchants. Ecological approaches emphasize tailoring specific interventions to the cognitive and physical skills of adolescents and to the social world in which they live. Local enforcement of laws designed to protect adolescents is an important ecological factor in prevention. Significant overlap exists among these strategies. Ecological changes have an influence on legislation and behavior; structural changes have an effect on behavior and ecology. Legislative changes affect behavior, structures, and ecology and they work best when combined.

### Preventing Road Traffic Injuries

As per the Global action plan for road safety, 2013 designed by UN general assembly, the 5 pillars that guide national road safety plans and activities over the decade of action are— Road safety management; Safer roads and mobility; Safer vehicles; Safer road users; and Post-crash response.

A significant proportion of patients who sustain a road traffic injury incur permanent disability, through amputation, head injury or spinal cord injury. Access to pre-hospital services and quick evacuation and transport to hospital can save many lives and limit disability, since majority of these who die do so before they reach a hospital. Moreover, health care providers should be appropriately trained in emergency medical care, which is not the case in many low- and middle-income countries (LMICs) including India.

A number of effective strategies would, if implemented, reduce motor vehicle-related injuries in adolescents. Among the most important strategies are graduated licensing, safety belt and helmet use. Wearing a standard, good quality motorcycle helmet can reduce the risk of death by 40% and the risk of serious injury by over 70%. Seat belt usage protects the driver and the occupants from severe crash injuries. It reduces the risk of a fatal injury by up to 50% for front seat occupants, and up to 75% for rear seat occupants. Proper use of bicycle helmets can eliminate 65–88% of bicycle-related brain injuries and 65% of serious injuries to the face. Building a culture of safety for seat belts and helmet-wearing among adolescents with enforcement and education, has proven to be the most effective strategy.

One proven method for helping teens to become safer drivers is graduated driver licensing (GDL) which is prevalent in many developed countries. GDL systems work because they directly target the risk factors by giving newly licensed adolescent drivers experience under low-risk driving conditions. Many of these strategies have been successfully implemented within the context of parent management of teen driver intervention conducted within driver education.

### Prevention of Drowning

Victims of drowning have a very slim chance of survival after immersion. The victim loses consciousness after approximately 2 minutes of immersion and irreversible brain damage can take place after 4–6 minutes. Therefore, prevention strategies are more important.

Drowning prevention strategies should be comprehensive and include— engineering methods which help to remove the hazard, legislation to enforce prevention and assure decreased exposure, education for individuals and communities to build awareness of risk and to aid in response if a drowning occurs. Availability of properly-fitted and appropriate personal flotation devices, non-consumption of alcohol while boating and swimming appear to be effective drowning prevention strategies. Individual and community education on drowning awareness, risks associated with drowning and learning water survival skills appear promising strategies to prevent drowning. Similarly, ensuring the presence of lifeguards at swimming areas also appears to be a promising strategy to prevent drowning. Ensuring immediate resuscitation by increasing the capability of first responders to provide first aid in cases of drowning can decrease the potential severity of outcomes.

### VIOLENCE

Violence by young people is one of the most visible forms of violence in society. The main victims and perpetrators of such violence, almost everywhere, are adolescents and young adults. The World Health Organization defines violence as: *The intentional use of physical force or power, threatened or actual, against oneself, another person, or against a group or community, that either results in or has a high likelihood of resulting in injury, death, psychological harm, maldevelopment or deprivation.* The definition used by the World Health Organization associates intentionality with the committing of the act itself, irrespective of the outcome it produces.

Youth violence deeply harms not only its victims, but also their families, friends and communities. The problem of youth violence cannot be viewed in isolation from other problem behaviors. They also often display other problems, such as truancy and dropping out of school, substance abuse, compulsive lying, reckless driving and high rates of sexually transmitted diseases. However, not all violent youths have significant problems other than their violence and not all young people with problems are necessarily violent. There are close links between youth violence and another forms of violence. Witnessing violence in the home or being physically or sexually abused, for instance, may condition children or adolescents to regard violence as an acceptable means of resolving problems. Prolonged exposure to armed conflicts may also contribute to a general culture of terror that increases the incidence of youth violence. Understanding the factors that increase the risk of young people being the victims or perpetrators of violence is essential for developing effective policies and programmes to prevent violence.

### Epidemiology

In 2000, an estimated 1.6 million people worldwide died as a result of self-inflicted, interpersonal or collective violence, for an overall age-adjusted rate of 28.8 per 100,000 population. Nearly half of these 1.6 million violence-related deaths were suicides, almost one-third were homicides and about one-fifth were war-related. Though there is paucity of data on violence, especially in adolescents in India it has been reported in some studies. A school study from Chandigarh illustrates these facts: two-third of adolescents witnessed violence in life, 80% witnessed someone being bullied, 28% witnessed violence being caused by rods or sticks; 27% of subjects were victim of violence; 13% of subjects were perpetrators of violence. National study on child abuse (2007) found

that nearly every other boy and girls faced sexual abuse at least once. There is gross under-reporting of violence in our set up, though it is being reported almost daily in media in every part of India.

### Nonfatal Violence

Studies of nonfatal violence reveal that for every youth homicide there are around 20–40 victims of nonfatal youth violence receiving hospital treatment. As with fatal youth violence, the majority of victims of nonfatal violence treated in hospitals are males. The rates of nonfatal violent injuries tend to increase dramatically during midadolescence and young adulthood. Compared with fatal youth violence, nonfatal injuries resulting from violence involve substantially fewer firearm attacks and a correspondingly greater use of fists and feet, and other weapons, such as knives or clubs.

### Gender Based Violence: Indian Context

Girls are subjected to worse form of violence as documented by some of the Indian studies (**Box 2**). Violence against girls may range from emotional, (teasing, spreading rumors, humiliating, threatening) physical (slapping, beating, burning, murder) sexual (by manipulation, threats or physical force). Many of these forms of violence are under reported as they may take place amongst families or close relationship. Violence against girls can have serious health consequences to the girl or her future generation. It has been shown that young women who has experienced physical or sexual violence in married life has 1.5 times more chance of aborting compared to one who had not had similar experience.

#### BOX 2 Violence against girls in India

- 1 in 5 girls aged 15–19 who experienced sex before marriage were forced to engage in sexual behavior
- 1 in 3 married girls aged 15–19 have experienced emotional, physical and sexual violence from their husbands
- 2 in 5 women who were commercially exploited were minor girls.

### Forms of Violence

Violence can be *nonphysical*, i.e., verbal harassment, bullying or intimidation, verbal coercion, or expression in the form of body language, staring, glaring, gesturing, blocking access to entry or escape). The other form is *Physical*—sexual (abuse, incest, assault, rape), on sexual (hitting, kicking, biting, choking, punching, grabbing, pulling hairs or other body parts, with a weapon in the form of object like gun, knife, and stick or with hand, feet head, etc.

The WHO report places youth violence in a model within the context of three larger types of violence: self-inflicted, interpersonal, and collective. *Interpersonal violence* is subdivided into violence largely between family members or partners and includes child abuse. *Community violence* occurs between individuals who are unrelated. *Collective violence* incorporates violence by people who are members of an identified group against another group of individuals with social, political, or economic motivation. The types of violence in this model have behavioral links, in that child abuse victims are more likely to experience violent and aggressive interpersonal behavior as adolescents and adults. Overlapping risk factors exist for the types of violence, such as firearm availability, alcohol abuse, and socioeconomic inequalities. The benefit of identifying common risk factors for the types of violence lies in the potential of intervening with prevention efforts and gaining positive outcomes for more than one type of violent behavior. The model further acknowledges four categories that explore the potential nature of violence as involving *physical, sexual, or psychologic force, or deprivation*. Whereas, no model violence is universally acceptable, but WHO model does provide a useful

framework for understanding the complex patterns of violence taking place around the world, as well as violence in the everyday lives of individuals, families and communities.

### Etiology

Aggressive behavior and violence are interlinked. Some children exhibit problem behavior in early childhood that gradually escalates to more severe forms of aggression before and during adolescence.

### Life-Course Persistent Offenders

This group of adolescents commit the most serious violent acts and often continues their violent behavior into adulthood. Several longitudinal studies have shown that childhood aggression is a good predictor of violence in adolescence and early adulthood. In other words, those who are relatively more aggressive at a given age also tend to be relatively more aggressive later on, even though their absolute levels of violence may vary. There may also be progressions over time from one type of aggression to another. For instance, in a longitudinal study in Pittsburgh, PA, United States, of over 1500 boys originally studied at 7, 10 and 13 years of age, Loeber et al. reported that childhood aggression tended to develop into gang fighting and later into youth violence.

### Adolescence-limited Offenders

This group is relatively common. These young people engage in violent behavior over much shorter periods and show little or no evidence of high levels of aggression or other problem behaviors during their childhood. Majority of the violent youths belong to this group and they tend to discontinue their violent behavior after 1–3 years.

### Factors Contributing to Violence

Violence is learned behavior and cultural and social influences play a significant role in many of these intentional injuries. Some of the important factors contributing to violence in youth are enlisted in **Box 3**. The link between severe mental disorders and violent behavior are more closely linked for those with co-occurring alcohol or substance abuse or dependence. Moreover, inability to maintain proper social skills like establishment and maintenance of positive family and peer relations and poor resolution of conflict may put adolescents with these mental disorders at a high risk of physical violence. Some of the psychiatric disorders like *conduct disorder* and *oppositional defiant disorder* are also associated with violent behavior.

### Approach and Management

The medical personnel dealing with adolescents need to know how to screen, identify, treat and refer violence victims. Additionally, they should be familiar with the community programs available in the locality. The assessment of adolescent at risk or with history of violent behavior or victimization should be a part of the health maintenance visit of all adolescents. If there is any history of involvement in physical fight, carrying a weapon or if there are concerns about safety issues (HEADSS questionnaire), one should do more in depth analysis. The FIST's mnemonic (**Box 4**) is a very useful assessment tool for these kind of cases. One should not hesitate to take the help of a mental health professional if there is presence of any of these risk factors: substance use, physical or sexual abuse, consistent poor school performance, multiple incidents of trauma or encounter with law, or feature suggestive of mental health disorders.

The primary responsibilities of the attending clinician is two-fold: firstly to provide immediate medical care and secondly to ensure the safety and welfare of the adolescent. It has been broadly outlined in **Box 5**. Overall it requires lot of careful handling, sensitivity, empathy, and skill to manage these kind of cases. A very good description in structured format is given in the *job aids*

manual by WHO which can be accessed at [http://www.who.int/maternal\\_child\\_adolescent/documents/9789241599962/en/](http://www.who.int/maternal_child_adolescent/documents/9789241599962/en/).

Apart from initial stabilization after injury, the other steps in the management are evaluation and treatment of injury, evaluation

### BOX 3 Factors contributing to violence

- Poverty
- Gender
- Developmental issues (preoccupation with oneself, own appearance and image)
- Environment (violence at home, school)
- Interpersonal relations with family, friends and peers
- Poor school performance
- Absence of role models/mentors
- Substance abuse; childhood abuse
- Past history of violence or victimization
- Poor family functioning
- Media violence
- Mental health disorders (mental retardation, learning disabilities, ADHD and mood disorders)
- Other risk factors (use of anabolic steroids, gang tattoos, belief in one's premature death, preteen alcohol use, placement in juvenile delinquent centers)

### BOX 4 FISTS mnemonic to assess adolescents at risk of violence

**F: Fighting** (how many fights you had in last year? Which was the last?)  
**I: Injuries** (have you ever been injured? Have you ever injured someone else?)  
**S: Sex** (Has your partner hit you? Have you hit your partner? Have you ever been forced to have sex?)  
**T: Threats** (Has someone with a weapon threatened you? What happened? Has anything changed to make you feel safer?)  
**S: Self-defense** (What will you do if someone tries to pick a fight? Have you carried weapon in self-defense?)

Adapted from Knox L: American Medical Association 2002.

### BOX 5 Management of violence and assault in adolescents

- Prepare yourself and health facility to manage adolescents who have been assaulted
- Take a history
  - General medical history; detailed history of assault
  - Gynecological history (in case sexual assault in females)
- Physical examination
  - General physical examination
  - Genitoanal examination (in case sexual assault in males and females)
- Provide treatment
  - Physical violence
  - Sexual violence
- Record your findings and treatment provided
- Assess and ensure ongoing safety
- Provide information on findings of examination and treatment
- Arrange counseling and social support
- Arrange referrals if needed
- Arrange for follow-up visit

Adapted from adolescent job aid—a handy desk reference tool for primary level health workers: WHO; 2010.

of assault circumstances, psychological evaluation and support, treatment plan at discharge that is directed to protect the teenager from similar injuries, and minimize development of psychological disability. One has to remember that victims as well witness of violence are at risk for post-traumatic stress disorder, and future aggressive or violent behavior.

Apart from being sensitive toward the adolescent, the physician should be aware of the legal aspect of managing these cases as well, and if required should inform police as required by law. Depending upon the situation, the family, or the care taker, or the child welfare committee of the district or the child helpline can be contacted. Precautions should be taken while dealing with an adolescent who is a victim of violence including sexual violence. A detailed verbatim hand written history from the child and accompanying person mentioning the date, time, place, witness and other details of other history should be taken. For medical examination, a consent should be taken from the child or the parents and it should be done preferably by the doctor of same sex. Diagrammatic representation of anatomic parts and the injuries should be recorded along with the detailed general physical examination. Appropriate samples should be collected depending on the form of violence/abuse. The record should be kept confidential at a secured place. The cases of sexual or child abuse should be dealt by specially trained teams. The medical officer (MO) should be aware of Protection of Children from Sexual Offences Act 2012 (POSCO) while dealing with the cases of child abuse. For persistent violent and aggressive behavior multiple treatment modalities varying from cognitive behavioral therapy involving the individual and the family and pharmacotherapy are used simultaneously.

## Prevention

The most common interventions against youth violence seek to increase the level of protective factors associated with individual skills, attitude and beliefs. As per WHO report, broadly four types of approaches viz: individual, relationship, societal and community can be used for prevention.

- **Individual approaches** Concentrate on children as well as youths who have already displayed some violent tendencies by changing their attitudes and behaviors to avoid aggressive and violent behavior.
- **Relationship approaches** Focus on the family members of the victim, especially those with the potential to trigger aggressive or violent responses.
- **Community-based approaches** Raise public awareness in an effort to stimulate action by community members to reduce violence and protect vulnerable community members.
- **Societal approaches** Include broader advocacy and legislative actions, as well as societal and cultural environmental changes. Ideally prevention should start from the beginning and these are age group directed preventive measures as advised by WHO.

## SUICIDE AND SELF-HARM

Self-harm and suicide are major public health problems in adolescents, with rates of self-harm being high in the teenage years and suicide being the second most common cause of death in young people worldwide. Pediatricians and primary care providers should ask about depression and suicidal ideation at each adolescent visit and must be comfortable assessing suicide risk and knowing when to refer children and adolescents for mental health care.

### Self-Harm

Self-harm refers to intentional self-poisoning or self-injury, irrespective of type of motive or the extent of suicidal intent. Methods of self-injury are heterogeneous, including acts such

as self-cutting, jumping from heights and self-battery ingestion, with some authors also including nonrecreational risk taking. Self-harm (and suicide) in adolescents are the end products of a complex interplay between genetic, biological, psychiatric, psychological, social, and cultural factors (**Box 6**). Although international variation exists, findings from many community-based studies show that around 10% of adolescents report having self-harmed, of whom some will report some extent of suicidal intent underlying their self-harm. Such studies consistently show that self-harm is more common in female adolescents than in male adolescents. Presentation to hospital occurs in only about one in eight adolescents who self-harm in the community, being more common in those who take overdoses.

#### BOX 6 Risk factors for self-harm and suicide in adolescents

##### Sociodemographic and educational factors

- Sex (female for self-harm and male for suicide)—most countries\*
- Low socioeconomic status\*
- Lesbian, gay, bisexual, or transgender sexual orientation
- Restricted educational achievement\*

##### Individual negative life events and family adversity

- Parental separation or divorce\*
- Parental death\*
- Adverse childhood experiences\*
- History of physical or sexual abuse
- Parental mental disorder\*
- Family history of suicidal behavior\*
- Marital or family discord
- Bullying
- Interpersonal difficulties\*

##### Psychiatric and psychological factors

- Mental disorder\*, especially depression, anxiety, attention deficit hyperactivity disorder
- Drug and alcohol misuse\*
- Impulsivity
- Low self-esteem
- Poor social problem-solving
- Perfectionism
- Hopelessness\*

All the factors in the panel have been shown to be related to self-harm.

\*Shown to be related to suicide.

Adapted from Self-harm and suicide in adolescents By Hawton K, Saunders KEA, O'Connor RC. Self-harm and suicide in adolescents the lancet.com. 2012;379:2373-82.

## Epidemiology

World Health Organization estimates that nearly 900,000 people worldwide die from suicide every year, including about 200,000 in China and 170,000 in India. Global figures for suicide in the age group of 10–24 show that suicide is the second most common cause of death after road-traffic accidents—it is the third most common cause of death in male adolescents (after road-traffic accidents and violence). Globally, suicide is the most common cause of death in female adolescents aged 15–19 years. Suicide is uncommon before 15 years of age but increases in prevalence through adolescence (19.2 deaths per 100,000 male adolescents aged 15–24 years) and into adulthood (28.3 deaths per 100,000 men aged 25–34 years). A recent study by Patel et al. on *suicides in India* published in *Lancet* in 2012 present some interesting facts: About 3% of the surveyed deaths (2684 of 95,335) in individuals aged 15 years or older were due to suicide, corresponding to about 187,000 suicide deaths in India in 2010 in these ages. For suicide deaths at ages 15 years or older, 40% of suicide deaths in men (45,100 of 114,800) and 56% of suicide deaths in women (40,500 of 72,100) occurred at ages 15–29 years. A

15-year-old individual in India had a cumulative risk of about 1.3% of dying before the age of 80 years by suicide; men had a higher risk (1.7%) than did women (1.0%), with especially high risks in south India (3.5% in men and 1.8% in women). About half of suicide deaths were due to poisoning (mainly ingestions of pesticides), followed by hanging, burns and drowning. Overall the reported cases of suicide are just the tip of the iceberg, the actual number may be much higher.

## Etiology

Experts emphasize the presence of few predisposing factors, viz biological (e.g., serotonin imbalances), personality (e.g., perfectionism, impulsivity), and cognitive vulnerabilities (e.g., impaired social problem solving) combined with exposure to negative life events, including both early and recent life adversity, and psychiatric disorders to increase risk of self-destructive behaviors across the lifespan. The outcome could be due to further interplay between factors associated with the development of thoughts of self-harm or suicide (e.g., feeling defeated and trapped) and those that increase the likelihood that such thoughts will be translated into actual suicidal behavior (e.g., impulsivity, exposure to self-harm by others).

## Management

The vast majority of children and adolescents who complete suicide have some form of psychiatric illness. Assessment of suicidal ideation should be a part of each health visit in adolescence (HEADSS questionnaire). There is no evidence that discussing suicide with patients increases the likelihood that they will harm themselves. There is evidence that suicidal persons who seek medical care do not discuss suicidal thoughts, symptoms of depression, or patterns of drug use, unless specifically asked.

The first step of *suicide assessment* is that suicidal ideation should not be taken lightly. If a suicidal threat is labeled manipulative, power or control becomes a major issue influencing behavior, and the risk of suicide may increase. In the case of the adolescent who is seen after a suicide attempt, a thorough history regarding ingestion (including drug and alcohol) is necessary, and aggressive management of poisoning must be implemented as indicated.

The next step of suicide assessment is that the child or adolescent must be understood within the framework of biopsychosocial factors. A careful psychiatric history and a mental status examination are necessary to assess the risk of suicide completion. Pediatricians who are uncomfortable with psychiatric assessment should seek immediate consultation with a mental health professional. Signs and symptoms of mood disorders, conduct problems, chronic anxiety, or substance abuse suggest the need for intervention and indicate a risk of eventual suicide completion. Previous suicide attempts should also be documented. To identify precipitating events, the physician should carefully explore, in detail, the child's life during the 2–3 days before either the threat or the suicide attempt. When a suicidal patient has been seen in the physician's office, the physician should inform the parents and a psychiatric consultation should be obtained (*no-suicide contract* comes to play) with the patient. The parents should be notified. As many clients resist psychiatric consultation, the pediatrician should try and schedule a psychiatric consultation as early as possible. If possible, the patient should be admitted and adequate evaluation should be made of the patient's frame of mind and the family or environmental circumstances. The physician must pay careful attention to how the family and friends have responded to the patient's act. A hostile and angry family, as is frequently seen, necessitates a different disposition or resolution than a supportive, sympathetic, and understanding family. Some families may completely deny the seriousness of the behavior; this can be discouraging and provocative to the patient, whose act has been an attempt to compel a different response. Family members

should be counseled to examine their roles in the interactions that preceded the attempt, without being made to feel overly guilty. Psychiatric hospitalization is indicated when the individual continues to be actively suicidal, when he or she is found to have a major psychiatric disorder, or when major family problems complicate his or her ongoing protection.

### Prevention

Approaches (**Box 7**) to prevent self-harm and suicide can be divided into population-based measures, which are aimed at all young people (e.g., educational initiatives), and measures aimed at high-risk groups (e.g., individuals with a history of abuse, those who self-harm). Restriction of access to means for suicide is a key suicide prevention strategy in adolescents, especially because of the often impulsive nature of the behavior. For example, safe storage of pesticides in rural areas of developing countries, where ready availability means that suicide by pesticide ingestion is common.

#### BOX 7 Approaches to prevent self-harm and suicide in adolescents

##### Population measures

- School-based psychological well-being and skills training programmes
- Gatekeeper training (e.g., school teachers, peers)
- Screening to identify those who might be at risk
- Restriction of access to means used for self-harm and suicide
- Improved media reporting and portrayal of suicidal behavior
- Encouragement of help-seeking behavior
- Public awareness campaigns
- Help-lines
- Internet sources of help
- Reduction of stigma associated with mental health problems and help seeking.

##### Measures for at-risk populations

- Psychosocial interventions for adolescents at risk of self-harm or suicide (e.g., depressed adolescents, abused individuals, runaway children)
- Screening of those at risk (e.g., young offenders)
- Psychosocial interventions for adolescents who have self-harmed
- Pharmacotherapeutic interventions for adolescents at risk of self-harm or suicide.

### IN A NUTSHELL

1. Violence and injuries account for 9% of global mortality causing more than five million deaths every year.
2. Nearly 50% of the morbidity and mortality in adolescents stems from four behaviors: sexual activity, substance use and abuse, motor vehicle use, and interpersonal violence.
3. Adolescents are more likely to engage in risk-taking behaviors because judgment, decision-making, reasoning and impulse control do not fully mature until 20–25 years of age.
4. Adolescents are the prime population involved in road traffic injuries. Speeding, drunk-driving, improper usage of helmets, not wearing seat-belts are the most important risk factors.
5. Youth violence deeply harms its victims, and their families, friends and communities.
6. Girls are subjected to worse form of violence as documented by some of the Indian studies.
7. Adolescents are frequently involved in interpersonal and self-inflicted violence (including suicides).
8. Suicides in adolescents are the end products of a complex interplay between genetic, biological, psychiatric, psychological, social, and cultural factors.
9. The medical personnel dealing with adolescents need to know how to screen, identify, treat and refer violence victims.
10. The most common interventions against youth violence seek to increase the level of protective factors associated with individual skills, attitude and beliefs.

## Chapter 25.5

# Menstrual Disorders and Polycystic Ovary Syndrome

Amita Suneja, Richa Aggarwal

Menstrual disorders are a common problem in adolescents. Studies have shown worldwide that approximately 25% of girls have significant menstrual dysfunction affecting life activities and resulting in school absence. These disorders are often the source of anxiety for the patients and their families. The common menstrual disorders in adolescents include amenorrhea, abnormal/excessive uterine bleeding, dysmenorrhea and polycystic ovary syndrome (PCOS). In the adolescent clinic of our hospital in Delhi which is a tertiary center, 68% of girls attending the clinic presented with menstrual disorders, of which amenorrhea was the most common complaint (22% with primary amenorrhea and 11% with secondary amenorrhea), followed by oligomenorrhea (28%), menorrhagia with or without polymenorrhea accounted for 24% of cases, 10.6% of patients had dysmenorrhea and 2.8% girls presented with cryptomenorrhea.

### AMENORRHEA

The absence of menses in a girl of reproductive age is defined as amenorrhea, and is divided into *primary* and *secondary* types. Recently, the definition of primary amenorrhea has changed and an evaluation should be considered in the conditions given in **Box 1**. Secondary amenorrhea is defined as the absence of menses for 6 months in girls with previously irregular menstrual pattern, or in girls before the completion of the second gynecologic year. In girls with formerly regular cycles of 21–45 days, secondary amenorrhea is defined as the absence of menses for three consecutive months. The distinction between primary amenorrhea and secondary amenorrhea is somewhat arbitrary and there is a great deal of overlap. Any cause of secondary amenorrhea (including pregnancy) can also be a cause of primary amenorrhea. In general, however, for a patient with primary amenorrhea the suspicion should be high for the possibility of a chromosomal or structural abnormality.

#### BOX 1 Indications for evaluation of an adolescent for primary amenorrhea

- An adolescent who has not had menarche by 15 years of age
- An adolescent who has not attained menarche and more than 3 years have elapsed since thelarche
- An adolescent with no periods and no secondary sexual development by 13 years of age
- An adolescent with no periods by age 14 years
  - There is a suspicion of an eating disorder or excessive exercise
  - There are signs of hirsutism
  - There is suspicion of genital outflow obstruction

### Etiology

The common causes of amenorrhea in adolescents are listed in **Box 2**. In clinical practice, hypothalamic amenorrhea and PCOS are the most prevalent causes of amenorrhea in adolescents. However, the most common cause of primary amenorrhea in our series was tuberculosis which accounted for 20% of cases.

### Approach to Diagnosis

#### History

Presence of secondary sexual characteristics should be asked for specifically. History of any chronic illness, weight gain or loss,

#### BOX 2 Etiology of amenorrhea in adolescents

- *Hypothalamic*
  - Eating disorders
  - Immaturity of the HPO axis
  - Exercise-induced amenorrhea
  - Medication-induced amenorrhea
  - Chronic illness
  - Stress-induced amenorrhea
  - Tumor, irradiation
  - Kallmann syndrome
- *Pituitary*
  - Hyperprolactinemia
  - Prolactinoma
  - Craniopharyngioma
  - Isolated gonadotropin deficiency
- *Thyroid*
  - Hypothyroidism
  - Hyperthyroidism
- *Adrenal*
  - Congenital adrenal hyperplasia
  - Cushing syndrome
- *Ovarian*
  - Polycystic ovary syndrome
  - Gonadal dysgenesis (Turner syndrome)
  - Premature ovarian failure Ovarian tumor Autoimmune oophoritis

- *Uterine*
  - Pregnancy
  - Androgen insensitivity Uterine adhesions (Asherman syndrome)
  - Müllerian agenesis
  - Genital tuberculosis
  - Cervical agenesis
- *Vaginal*
  - Imperforate hymen
  - Transverse vaginal septum
  - Vaginal agenesis

Abbreviation: HPO, Hypothalamic-pituitary-ovarian axis.

and exercise habits should be elicited. Sexual history should be obtained confidentially, because pregnancy is a rare but possible cause of primary amenorrhea and the most common cause of secondary amenorrhea.

Social stressors may contribute to primary or secondary amenorrhea, and should be sought. Patient should be asked specifically about the medications she is taking, including any antipsychotic medication, contraceptive use, and illicit drug use. The review of systems should include discussion of acne or unwanted hair growth, weight changes, mood changes, disordered eating attitudes and behavior, change in bowel habits, abdominal pain, headaches, visual changes, galactorrhea, athletic participation and vaginal discharge. Family history should focus on any potential endocrine disorders in first-order relatives, including thyroid disease, diabetes, PCOS, and infertility and any constitutional delay of menses in siblings.

### Physical Examination

The physical examination of the girl presenting with amenorrhea begins with a general assessment including height, weight and body mass index (BMI calculation). Girls who are overweight are more likely to have an endocrinopathy (hypothyroidism, Cushing syndrome), whereas underweight patients may have a deficit of calories (eating disorder or bowel disease such as inflammatory bowel disease or celiac disease). The patient with exceptionally short stature with or without other features such as webbed neck,

widely spaced nipples, shield chest, and high arched palate, and primary amenorrhea points toward Turner syndrome (45,X) or mosaicism (46,XX/45,X).

Palpation of thyroid gland and Tanner staging of breast development and pubic hair has to be done. Breasts should be examined for presence of galactorrhea. A brief neurological examination may include an assessment of the ability to smell, fundoscopic examination and screening visual field tests by confrontation. The presence of hirsutism, acne and acanthosis nigricans should be looked for.

The gynecological assessment involves inspection of the external genitalia to determine if the girl has clitoromegaly and a normal hymenal opening and whether there is estrogen effect on the hymen and anterior vagina. Normal breast development and an estrogenized vagina implies ovaries are producing estrogen. To assess the patency and length of the vagina in a virgin patient, a saline moistened cotton-tipped applicator can be gently inserted into the hymen opening to assess the depth of the vagina (7–8 cm is average for a postpubertal young woman). In a patient with vaginal agenesis, the applicator can be inserted only 0.5–2 cm. If there is any question of anatomic abnormality, pelvic ultrasonography should be performed at an experienced center.

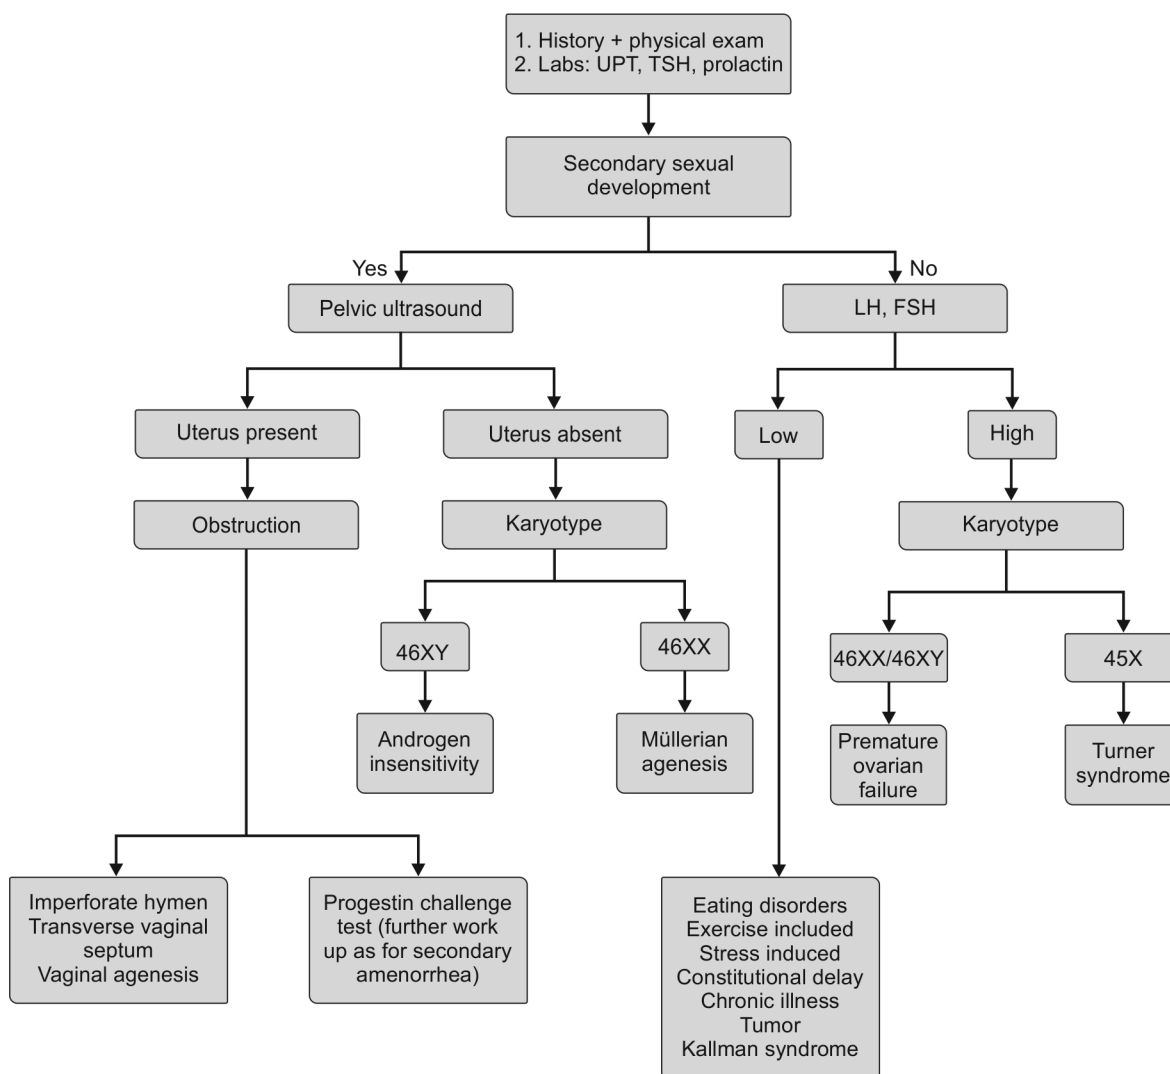

## Laboratory Evaluation

A sensitive pregnancy test must be part of the initial evaluation of any girl with amenorrhea, regardless of the reported sexual history. Thyroid-stimulating hormone (TSH) and prolactin (PRL) levels should be done in all patients, as amenorrhea may be the result of hyperprolactinemia or thyroid gland dysregulation which are readily correctable by treatment. Further evaluation of adolescents with primary amenorrhea depends upon the presence or absence of secondary sexual characteristics (**Flow chart 1**).

### Primary Amenorrhea and Absence of Secondary Sexual Characteristics

The assessment should begin with measurement of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Elevated gonadotropin levels imply that the cause of the delayed puberty lies within the gonads, while low or normal FSH and LH levels point to constitutional delay of puberty, pituitary dysfunction, or hypothalamic disorders. In patients with elevated gonadotropin levels, pelvic ultrasound imaging is done to see the presence of follicles in the ovaries, and the thickness of the endometrium. Absence of follicles in ovaries or small, streak gonads along with thin or atrophic endometrium suggests ovarian

**Flow chart 1** Diagnostic evaluation of primary amenorrhea

Abbreviations: UPT, urine pregnancy test; LH, luteinizing hormone; FSH, follicle stimulating hormone, TSH; thyroid stimulating hormone.

failure. Karyotype study will contribute in the differential diagnosis between ovarian failure, gonadal dysgenesis, Turner syndrome, and androgen insensitivity syndrome, as these are the commonest causes of primary amenorrhea with underlying chromosomal deficiencies. **Table 1** describes the various congenital syndromes leading to hypergonadotrophic hypogonadism.

### Primary Amenorrhea and Normal Pubertal Development

These girls should undergo rectoabdominal gynecologic examination and pelvic ultrasound to exclude the existence of a congenital anatomic defect of the outflow tract. Absence of uterus with absent or short vagina suggests Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome or testicular feminization syndrome, the differentiating features of which are given in **Table 2**. If the possibility of congenital malformations of the genital tract has been ruled out, further work up is similar to that for girls who experience secondary amenorrhea.

### Secondary Amenorrhea

The assessment of an adolescent patient should begin with pregnancy exclusion and be followed with search for signs of clinical hyperandrogenism (**Flow chart 2**). In the presence of clinical hyperandrogenism, FSH, LH, testosterone, and dehydroepiandrosterone sulfate (DHEA-S) should be measured and further investigations in the direction of PCOS or congenital adrenal hyperplasia are done. However, in patients with absence of clinical hyperandrogenism and in patients with clinical hyperandrogenism but with normal serum androgen levels, progesterone challenge test (PCT) should be performed with medroxyprogesterone 5–10 mg once daily or 200–300 mg daily micronized progesterone for 7–10 days to assess the levels of circulating estrogens and their effect on the endometrial function. If PCT is positive, indicates ovaries are normally producing estrogen and anovulation is the cause. The most likely diagnosis is either immaturity of the hypothalamic-pituitary-ovarian (HPO) axis if the patient is within 2–3 years of menarche. If PCT

is negative, challenge with sequential estrogen-progestin regime is given and if the patient does not bleed, endometrial dysfunction should be suspected. However, if the patient bleeds on estrogen-progestin, absence of estrogen is the cause which may be due to ovarian failure, pituitary failure or hypothalamic failure. Further measurement of FSH, LH is indicated.

If elevated FSH and LH levels are a persistent finding in several consecutive measurements, along with normal TSH and prolactin (PRL) levels, the most probable cause of the secondary amenorrhea is ovarian failure. When the above mentioned hormone levels are low or within the normal range, pituitary or hypothalamic causes are the probable etiologies.

### Management

While managing an adolescent patient with amenorrhea, the first and foremost thing is to alleviate anxiety by detailed counseling and reassurance. Therapy should be directed at treating the underlying cause of the amenorrhea, if possible. In girls with no pubertal development due to hypoenestrogenism either due to ovarian failure, hypopituitarism or hypothalamic disorders, estrogen therapy is given in three phases:

**Phase 1** For induction of breast development, generally lower doses are given (25 mcg estradiol patches, 0.3 mg of conjugated estrogens) and continued for 6–12 months. Oral contraceptives are not recommended for initial therapy, as they contain higher levels of estrogen, as well as progestin, throughout the cycle, which is not physiological.

**Phase 2** Establishment of normal menses, completion of breast development and acquisition of normal bone mass. The estrogen dose is increased (50 mcg estradiol patches, 0.625 mg of conjugated estrogens or 20 mcg ethinyl estradiol). A short course of progestin (5 or 10 mg medroxyprogesterone) may be added within 2–3 months of phase 2 for 5 days in a month along with continuous estrogen to give a predictable onset of menses. This dose of progestin is given only until breast development is completed (6–12 months) and then the progestin dose is increased to 10 days and ultimately to 12–14 days.

**Phase 3** Long term maintenance of a normal estrogen state, both estrogen and progestin are continued till the expected age of menopause. Estrogen (50–100 mcg estradiol patches, 0.625–1.25 mg of conjugated estrogens or 20 mcg ethinyl estradiol) daily plus progestin for 12–14 days each month or oral contraceptives are given. Most adolescents prefer monthly menses, and thus, progestin is prescribed monthly. Some adolescents like athletes prefer a minimum number of withdrawal menses and hence, can be prescribed daily estrogen cycled every 60–90 days with progestin for 14 days. If the girl is well estrogenized with anovulation as the cause of amenorrhea, menstrual cycles can be induced with cyclic progestins every 1–3 months.

In addition to hormone therapy, calcium and vitamin D supplementation daily should be advised. Exercise is also important for hypoenestrogenic adolescents to promote bone formation and cardiovascular fitness; however, it needs to be limited in girls with anorexia nervosa.

In anorexia nervosa, psychological and nutritional rehabilitation is associated with resumption of menses in approximately two-thirds of patients within one year. Administration of dopamine receptor agonists, like bromocriptine and cabergoline, is the treatment of choice for hyperprolactinemia.

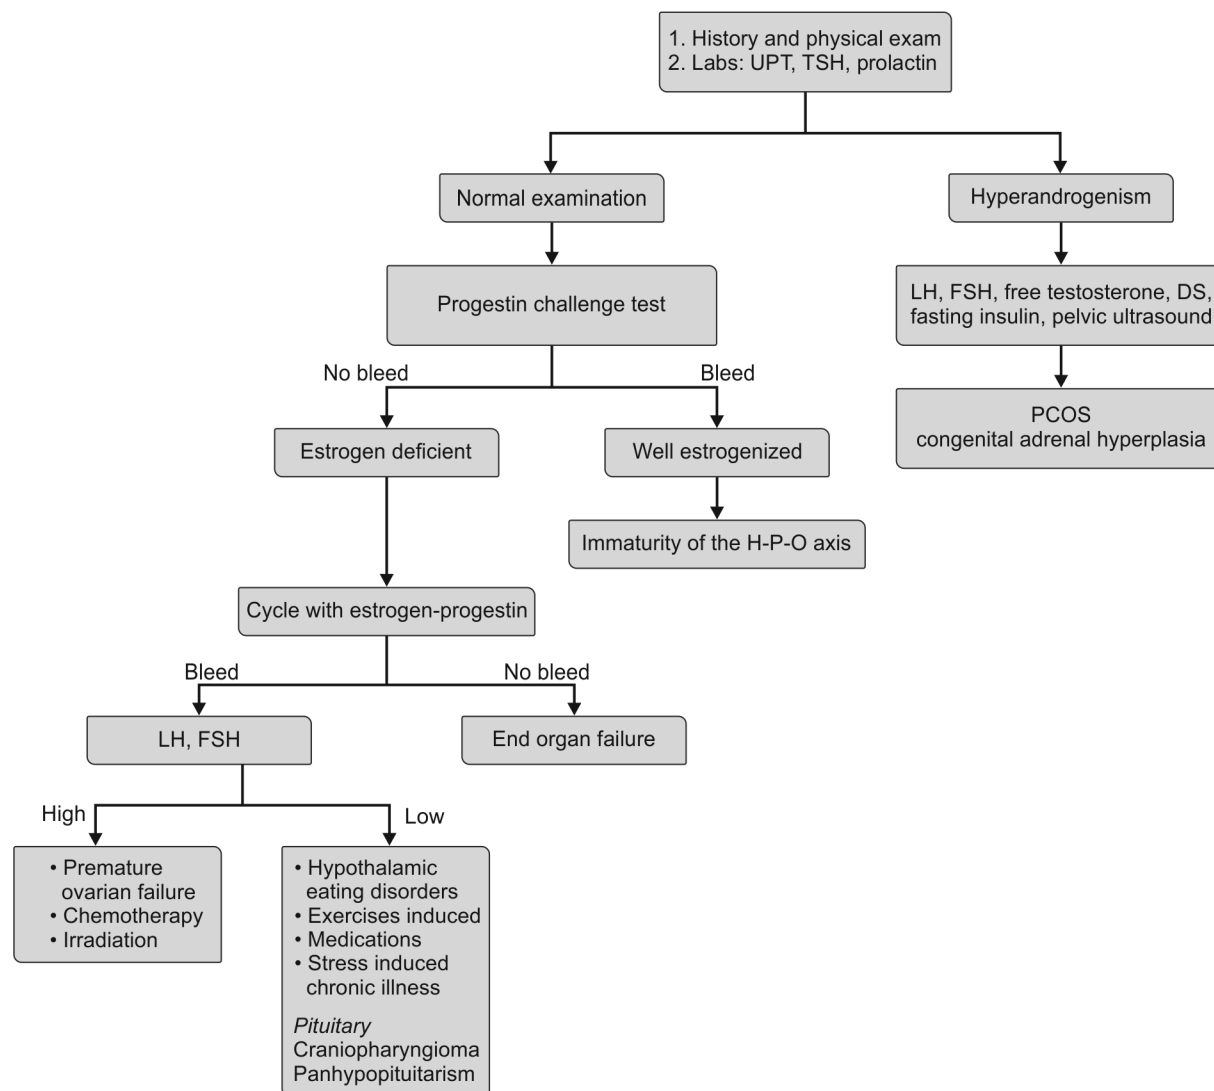

Surgical excision of the septum has to be done in cases of transverse vaginal septum. For patient with vaginal agenesis, use of manual dilators to create functional vagina can be done under supervision failing which, surgical creation of neovagina (vaginoplasty) is required so as to provide the girl the opportunity to have a normal sexual life. However, since patients of MRKH

**Table 1** Congenital syndromes of hypergonadotrophic hypogonadism

Syndrome	Karyotype	Clinical features
Turner syndrome	45 XO	Short stature, sexual infantilism, webbed neck, streak gonads
Swyer syndrome	46XY	Lack of sexual development, streak gonads, normal female testosterone
Pure gonadal dysgenesis	46XX	Premature menopause due to accelerated germ cell loss
Perrault syndrome	46XX	Neurosensory deafness
Mixed gonadal dysgenesis	45X/46XY	Streak gonad on one side, dysgenetic or normal testis on other side

**Table 2** Comparison of Mayer-Rokitansky-Küster-Hauser (MRKH) versus testicular feminization syndrome

Features	MRKH syndrome	Testicular feminization syndrome
Karyotype	46XX	46XY
Sexual hair	Normal female	Absent to sparse
Heredity	Not known	X-linked recessive
Testosterone levels	Normal female	Normal/slightly elevated
Other anomalies	Present	Rare
Risk of gonadal neoplasia	Not raised	Increased

**Flow chart 2** Diagnostic work-up of an adolescent with secondary amenorrhea

**Abbreviations:** HPO, hypothalamic-pituitary-ovarian axis; LH, luteinizing hormone; FSH, follicle stimulating hormone; TSH, thyroid stimulating hormone; PCOS, polycystic ovary syndrome.

syndrome have normal ovaries, they can have children by oocyte retrieval, fertilization of the egg in vitro, and a gestational carrier. Uterine transplantation is a viable option, but so far transplanted uterus has not delivered a viable fetus. The presence of Y chromosome in the karyotype requires gonadectomy as soon as the diagnosis is made because of the risk of development of neoplasia and the risk of virilization. However, in patients with testicular feminization, the surgery should be performed once puberty is achieved to allow for breast development and the attainment of the maximum expected adult stature. Estrogen replacement therapy should be given after gonadectomy.

## DYSMENORRHEA

Dysmenorrhea refers to recurrent, crampy lower abdominal pain that occurs during menstruation. Primary, or functional, dysmenorrhea is pain that occurs in the absence of pelvic disease and is more common as compared to secondary dysmenorrhea, which occurs secondary to a pathologic process.

## Etiology

The prevalence of dysmenorrhea among adolescent females ranges from 60% to 93%. Many adolescents report limitations of daily activities, such as missing school, sporting events, and other social activities, however, only 15% of females seek medical advice for menstrual pain, signifying the importance of screening all adolescent females for dysmenorrhea.

The symptoms are caused by prostaglandin E<sub>2</sub> and F<sub>2α</sub> (alpha) secretion or an elevated PGF<sub>2</sub> alpha: PGE<sub>2</sub> ratio. These compounds can cause dysrhythmic uterine contractions, hypercontractility, and increased uterine muscle tone leading to uterine ischemia.

## Clinical Features

### Primary Dysmenorrhea

It is usually associated with ovulatory cycles, hence presents in the second or third gynecologic year, however, it may occasionally accompany anovulatory cycles, especially if heavy bleeding and clots are present. The pain may be associated with headache,

nausea, vomiting, dizziness or diarrhea. The symptoms typically begin several hours prior to the onset of menstruation and continue for one to three days. The severity of the disorder depends upon the severity of menstrual pain, presence of systemic symptoms, and impact on daily activities.

### Secondary Dysmenorrhea

It usually develops years after menarche and can occur with anovulatory cycles and this may be associated with uterine and pelvic pathology such as intrauterine contraceptive device (IUCD), endometriosis, pelvic inflammatory disease (PID), cervical stenosis, a submucosal fibroid or an endometrial polyp. The pain often begins 1–2 weeks prior to menses and persists until a few days after the cessation of the bleeding.

### Approach to Diagnosis

#### History

A complete menstrual history, onset and duration of cramps, presence of nausea, vomiting, diarrhea, back pain, dizziness, or headache during menstruation, impact of symptoms on daily activities, medication taken for pain relief and their perceived effectiveness and sexual history should be taken.

In adolescents with dysmenorrhea from menarche that progresses steadily, obstructive genital tract abnormalities or endometriosis should be considered. Adolescents with history of pelvic infections may develop adhesions that result in pelvic pain, especially during menstruation.

#### Physical Examination

A pelvic examination is generally not required in adolescents presenting with typical symptoms of primary dysmenorrhea. However, if the history is suggestive of an organic disease or any congenital malformation of the genital tract, or if the patient does not respond to the conventional therapy of primary dysmenorrhea, a complete pelvic examination is indicated or a rectoabdominal examination is advised if the patient is virgin to exclude adnexal tenderness and masses. It is not uncommon to detect an abdominal lump in cases of Müllerian anomalies.

### Laboratory Investigations

Laboratory testing or imaging is not routinely required to make a diagnosis of primary dysmenorrhea. However, specific investigations may be ordered when secondary dysmenorrhea is suspected. For girls who suffer from dysmenorrhea refractory to first line therapy, or in whom pelvic examination is impossible or unsatisfactory, ultrasound may uncover a pelvic mass or an obstructing Müllerian malformation. Ultrasonography cannot detect subtle signs of organic diseases such as uterosacral ligament tenderness or nodules and cervical motion tenderness. MRI is a useful adjunct in diagnostic pelvic pathology in young girls.

### Treatment

Primary dysmenorrhea may result in significant school absence and lost productivity, so aggressive and evidence-based treatment is warranted. [Nonsteroidal anti-inflammatory drugs, (NSAIDs), mefenamic acid, ibuprofen, naproxen, etc.] are considered the first line of therapy. In randomized trials of NSAIDs, approximately 70–90% of patients have effective pain relief. NSAIDs should be started at the onset of menses and continued for the first one to two days of the menstrual cycle or for the usual duration of crampy pain. However, with severe symptoms, NSAIDs should be started one to two days prior to the onset of menses. Adequate rest, sleep, hot fomentation, acupuncture and regular exercise may help in some women.

If NSAIDs do not control symptoms after two to three cycles, a trial of oral contraceptive (OCPs) may be indicated. OCPs reduce menstrual pain by eliminating ovulation and by thinning the endometrial lining; leading to reduced synthesis of prostaglandins. In severe cases, extended cycle OCP regimens (e.g., 84 active pills, followed by 7 placebos) may be used to eliminate menses. In a sexually active female, OCPs may be considered the first line of therapy because they serve a dual purpose: prevention of both pregnancy and dysmenorrhea. If there is no relief with either NSAIDs or OCPs, both can be prescribed simultaneously.

In case of secondary dysmenorrhea, treatment of the underlying cause is very important. Dilation of a narrow cervical os may give 3–6 months of relief (and allows diagnostic curettage if needed). Other surgical measures (e.g., myomectomy, polypectomy, or dilation and curettage) may be needed in some patients. But these are usually not required for adolescent girls. Presacral neurectomy and division of the sacrouterine ligaments may help selected patients.

### ABNORMAL UTERINE BLEEDING

Abnormal uterine bleeding is reported commonly during adolescence. Pediatric practitioners must know what is normal in order to assess patients accurately. A normal period usually lasts 3–7 days. The normal interval between menses in adolescents may be between 21 and 45 days, although 21–35 days is more common. The median blood loss during each cycle is 30–40 mL which usually translates into 10–15 soaked tampons or pads per cycle; the upper limit of normal is 80 mL.

Menorrhagia or heavy menstrual bleeding (HMB) includes duration greater than eight days, flow greater than 80 mL/cycle or subjective impression of heavier-than-normal flow (i.e., more than six full pads or tampons per day, soaking through a pad within 1 hour, soaking through bedclothes or passage of clots); metrorrhagia means irregular bleeding, and menometrorrhagia means heavy and irregular bleeding; polymenorrhea is bleeding occurring at less than 21 days.

### Etiology

The differential diagnosis of abnormal vaginal bleeding is vast and is given in **Box 3**. The most common cause of abnormal uterine bleeding in adolescents is anovulatory cycles secondary to a delay in maturation of the negative feedback loop, whereby rising estrogen levels suppress FSH secretion. This results in a constantly proliferative endometrium with irregular shedding. In a study of hospitalized adolescents with heavy menstrual bleeding, 74%

#### BOX 3 Differential diagnosis of abnormal uterine bleeding in the adolescent girl

- *Anovulatory*
- *Bleeding disorders*: Thrombocytopenia (e.g., idiopathic thrombocytopenic purpura, leukemia, aplastic anemia, chemotherapy)
- *Coagulation disorders*: von Willebrand disease, liver dysfunction, vitamin K deficiency
- *Hypothalamic cause*: Excessive exercise, psychological stress
- *Endocrine disorders*: Hypo- or hyperthyroidism, adrenal disease, hyperprolactinemia, PCOS, primary ovarian insufficiency
- *Systemic diseases*: Diabetes mellitus, renal disease, liver disorders
- *Pregnancy-related complications*: Abortion, ectopic pregnancy, gestational trophoblastic disease, complications of termination procedures
- *Structural defects*: Submucous myoma, congenital anomalies, Polyp
- *Infection*: Pelvic inflammatory disease, endometritis
- *Neoplasia*: Hormone secreting ovarian tumors, prolactinoma, adrenal tumors, endometrial cancer (rare)
- *Medications*: Hormonal contraceptives, anticoagulants, platelet inhibitors, androgens, spironolactone, antipsychotics

were diagnosed to have anovulatory dysfunctional bleeding, 19% had coagulation defects and rest 7% had other causes. Although most episodes of abnormal bleeding do not cause acute medical complications, bleeding can be traumatic for young patients and their families.

## Approach to Diagnosis

### History

In evaluation, the possibility of pregnancy should be kept first, because pregnancy complications presenting with bleeding, such as ectopic pregnancy, can be life threatening. All patients should be asked privately about the sexual history and in sexually active adolescents, it is important to enquire about contraceptive use and testing for gonorrhea and *Chlamydia trachomatis* should be performed.

Menstrual history should include detailed information about menarche; the timing, duration, and quantity of bleeding during recent menstrual cycles; and/or abnormal bleeding episodes. The history should include the number of pads used per day, passing blood clots, the need to change sanitary protection during the night. For patients with heavy regular, cyclic flow since menarche, a bleeding disorder such as von Willebrand disease is more likely. It is important to establish whether the bleeding is ovulatory or anovulatory. Regular cycles associated with premenstrual symptoms and dysmenorrhea usually imply ovulatory bleeding. Irregular cycles suggest anovulatory cycles, which may be due to an underlying endocrinopathy. Intermenstrual bleeding suggests anatomic disease (cervicitis), pregnancy related complications or breakthrough bleeding associated with use of hormonal contraception.

Questions about weight changes, exercise habits, acne, hirsutism, headaches, visual changes and chronic illness should be asked. Girls should be asked about bleeding from other sites and symptoms of acute or chronic anemia (e.g., epistaxis, gum bleeding, easy bruising, postoperative bleeding, lightheadedness, syncope, fatigue, weakness, headache).

Family history of bleeding tendencies (especially during childbirth and surgical procedures), endocrinopathies, and infertility should be elicited. Clinicians also should ask about antipsychotic and antiepileptic medications that may cause irregular bleeding, and aspirin and other anticoagulants, which may worsen bleeding.

### Physical Examination

Physical examination should include orthostatic vital signs for those with heavy bleeding. Sometimes resting tachycardia or orthostatic hypotension may be the only sign of severe anemia. The general examination should include measurement of height, weight, palpation of breast and thyroid, evaluation for signs of androgen excess (hirsutism; acne; male pattern balding), examination of the skin for presence of petechiae and/or bruising, acanthosis nigricans, examination of the optic fundi and visual field testing to evaluate the possibility of a pituitary tumor.

Palpation of the abdomen might diagnose an undetected pregnancy or an ovarian mass. Pelvic and bimanual examination is indicated for sexually active patients to screen for cervicitis and PID. In virginal patients who have longstanding ongoing bleeding, a rectoabdominal examination or transabdominal pelvic ultrasonography may be helpful.

### Laboratory Investigations

Laboratory testing should consist initially of a urine pregnancy test and a complete blood count, including platelet count to assess

the severity of bleeding. Other laboratory testing may be indicated depending upon the severity and the nature of the symptoms.

For severe bleeding or with hemorrhage since menarche, coagulation studies including prothrombin time/international normalized ratio, partial thromboplastin time, and Von Willebrand panel are indicated. For irregular bleeding, screening for endocrinopathies should be conducted by measuring FSH, LH, TSH, and prolactin, as well as androgen levels for girls with signs of hyperandrogenism on examination. Abdominal ultrasonography is warranted for girls presenting with a pelvic mass or if a uterine anomaly is suspected, or bimanual examination not possible in an adolescent with significant bleeding.

## Management

The goals of management include establishment and/or maintenance of hemodynamic stability, correction of acute or chronic anemia, return to a pattern of normal menstrual cycles, prevention of recurrence and prevention of long-term consequences of anovulation. The preferred treatment of abnormal uterine bleeding in adolescence is medical (**Table 3**); surgical intervention rarely is indicated. All treatment regimes must include iron replacement, although this therapy can be overlooked easily during the acute presentation and management.

Bleeding can be controlled with either combined OCPs or with progestins alone. OCPs reduce menstrual loss and establish a regular pattern of withdrawal bleeding. However, intravenous estrogen is required rarely in some patients who are actively bleeding and cannot tolerate oral medications in a dose of conjugated estrogens 25 mg every 4 hour for 2–3 doses followed by progestin.

A progesterone only preparation like **norethisterone** may be used if estrogen is contraindicated or if contraception is not desired. In our clinical experience, norethisterone controls bleeding in majority of patients. It is given in a dose of 10 mg thrice daily till the bleeding stops and then tapered off to 10 mg twice daily for 3 days followed by a dose of 5 mg twice daily for 21 days. Progestin-eluting intrauterine device (IUDs) may be an option in some cases.

Menstrual suppression using gonadotropin-releasing hormone (GnRH) analogs is generally avoided in adolescents because of their negative effects on bone mineralization. Antifibrinolytics such as tranexamic acid interfere with the breakdown of blood clots and thus stop or slow down bleeding; these agents may be used alone or along with OCPs.

If medical therapies fail to control bleeding within 24–36 hours in an ill patient, the possibility of pelvic pathology should be excluded by ultrasound, anesthesia examination, and rarely, dilation and curettage.

Once the acute episode of bleeding is controlled and the initial course of hormonal therapy is complete, further management depends upon the presence of persistent anemia and the desire for contraception. Low-dose combination OCP pills should be continued in girls who desire contraception and in those who required IV conjugated estrogen for initial control. Progesterone therapy may be used in girls with moderate or severe anovulatory uterine bleeding who were initially controlled with progestin-only regimens and do not desire contraception. As a general rule, hormonal therapy is continued for 3–6 months when possible either as 21 day cycle or extended cycle of 3 months or longer until the hematocrit returns to normal.

## POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome (PCOS) is the most common endocrinopathy affecting up to 10% of women of reproductive age. The incidence is still increasing because of the change in lifestyle including sedentary habits, increasing intake of junk food and higher stress levels. Young women with PCOS present with amenorrhea

**Table 3** Management of abnormal uterine bleeding based on severity of bleeding

	<i>Mild bleeding</i>	<i>Moderate bleeding</i>	<i>Severe bleeding with moderate anemia</i>	<i>Severe bleeding with severe anemia</i>
Hb	> 11g/dL	10–11g/dL	8–10 g/dL	< 7 g/dL
Anemia correction	Oral iron	Oral iron	Oral iron	Blood transfusion
Treatment	Reassurance	Progestin/OCPs	Progestin/OCPs	OCPs/conjugated estrogen
OCPs dosage	1 pill daily for 21 days	1 pill BD till bleeding stops and then 1 OD × 21 days	1 pill QID × 2–4 days and then, 1 TDS × 3 days, then 1 BD × 2 weeks till Hb normal	1 pill 4–6 hourly till bleeding slows, then 1 QID × 2–4 days; 1 TDS × 3 days; 1 BD × 2 weeks till Hb normal
D & C	Never done	Not done	Not required	Required for recurrence or treatment failure
Follow-up	Monthly	Weekly, then monthly	Weekly, then monthly	Daily, then weekly

or oligomenorrhea and signs of hyperandrogenism, including hirsutism, acne, scalp hair loss, seborrhea, or hyperhidrosis. They are often, but not always, overweight. The diagnosis of PCOS has lifelong implications with increased risk for metabolic syndrome, type 2 diabetes mellitus, and possibly cardiovascular disease and endometrial carcinoma.

There are three sets of criteria for diagnosis of PCOS given in **Table 4**. Generally, the NIH criteria are preferred in adolescents which include patients with anovulatory cycles and clinical or biochemical evidence of hyperandrogenism, with or without polycystic ovaries on ultrasonography, in whom other diagnoses (e.g., late-onset congenital adrenal hyperplasia and thyroid disease) have been excluded. The Androgen Excess Society guidelines also include those patients with normal menses, but have biochemical or clinical hyperandrogenism and also polycystic ovaries on ultrasonography. New criteria, Amsterdam workshop (2010)—all these elements of Rotterdam criteria should be present in teenagers to make the diagnosis of PCOS.

### Pathogenesis

Patients with PCOS have an increased LH pulse frequency and amplitude which act on ovarian theca cells and increase androgen production. Intraovarian androgen excess appears to be responsible for both anovulation and the formation of multiple ovarian cysts (which are actually small ovarian follicles that are hindered in developing a dominant follicle). Majority of women with PCOS have insulin resistance and compensatory hyperinsulinemia; these abnormalities are independent of BMI. Insulin decreases serum hormone binding globulin (SHBG) and hence increases free testosterone levels. The so called HAIR-AN

syndrome (hyperandrogenism, insulin resistance and acanthosis nigricans) is used to describe the severe end of spectrum.

### Approach to Diagnosis

#### History

Apart from a detailed menstrual history, history of premature pubarche, weight changes especially related to puberty, and duration, location and progression of unwanted hair growth should be sought. Drug history (valproate, anabolic steroids in athletes) and family history of hirsutism, PCOS, infertility, diabetes or hyperinsulinemia should be asked.

#### Physical Examination

Given the high prevalence of metabolic syndrome associated with PCOS, blood pressure, BMI and waist circumference should be measured. Evidence of androgen excess (hirsutism, acne, etc.), evidence of hypo or hyperthyroidism, presence of galactorrhea may help arrive at a diagnosis. Objective scoring of hair growth by Ferriman-Gallwey scoring system allows for measurement of the severity of hirsutism. Although a thorough pelvic examination is essential in older women; it is rarely needed in the adolescents, especially during the 5 years following menarche, except if there is contact bleeding or if the possibility of an STD cannot be excluded.

### Laboratory Investigations

As in all other menstrual complaints, a urine test to rule out pregnancy is mandatory. Other tests for evaluation for PCOS includes measuring LH, FSH, TSH, and prolactin levels to exclude other disorders, as well as obtaining serum levels of testosterone, free testosterone, and dehydroepiandrosterone (DHEAS). Most patients with PCOS have serum testosterone concentrations below 150 ng/dL.

The role of ultrasonography is to exclude the rare, but serious adrenal or ovarian tumor and ovarian pathology. The Rotterdam criteria define PCO as the presence of more than 12 follicles measuring 2–9 mm in diameter or ovarian volume more than 10 mL in at least one ovary. The classic peripheral pattern of a *string of pearls* is no longer necessary for making a diagnosis of PCOS.

Additional laboratory testing to detect metabolic abnormalities include fasting lipid profile and oral glucose tolerance test every 2 years.

### Management

Lifestyle modification including weight reduction by change in dietary habits and regular exercise should be advised in all obese patients with PCOS. **Table 5** summarizes the therapeutic options in PCOS, based on symptoms.

The endocrinologic therapy aims at reducing the excess production of androgens, reducing serum free androgen levels

**Table 4** Different diagnostic criteria for polycystic ovary syndrome (PCOS)

<i>Criteria</i>	<i>Hyperandrogenism</i>	<i>Oligo/anovulation</i>	<i>Polycystic ovaries</i>
National Institutes of Health (NIH)	+	+	±
Rotterdam criteria (if 2 of 3 present)	+	+	+
Androgen Excess Society criteria	+	± (either of two)	± (either of two)
Amsterdam criteria (all 3 should be present)	+	+	+

**Table 5** Therapeutic options in polycystic ovary syndrome (PCOS) based on symptoms

Chief complaint	First line therapy
Oligomenorrhea	Estrogen/progestin
Hirsutism, mild	Estrogen/progestin
Hirsutism, moderate to severe	Estrogen/progestin plus antiandrogen
Overweight	Exercise/nutrition plus metformin
Infertility	Ovulation induction

by increasing androgen binding to plasma-binding proteins and blocking androgen action at the level of target organs (e.g., hair follicle). The mainstay of treatment for PCOS includes three options: cyclic use of progestins to induce withdrawal bleeding; use of oral contraceptives pills to reduce ovarian androgen production and increase steroid hormone binding globulin; and use of metformin to lower circulating insulin levels and reduce ovarian steroid hormone production.

Oral contraceptive (OCPs) are the best option for sexually active young women who do not desire a pregnancy or who have menstrual irregularity and in those with hirsutism and acne; OCPs act by regularizing cycles, progestin inhibits endometrial proliferation, preventing hyperplasia, estrogen inhibits the activity of the hypothalamic-pituitary-gonadal axis, reducing ovarian androgen production as well as increasing sex hormone binding globulin (SHBG) levels. Unwanted hair growth improves in 50–70% of hirsute women.

In adolescent who is not sexually active and does not have significant hirsutism or acne, menses can be regulated with cyclic progestin only therapy. Metformin is particularly helpful for those with glucose intolerance. Metformin reduces insulin concentrations, promote ovulation, and lower androgen levels. Therapy is started with 500 mg daily before the evening meal, with an increase in the dose by 500 mg per week to the effective dose of 1500–2000 mg daily, as tolerated. Metformin promotes ovulation, so this drug should not be the sole therapy in sexually active teenagers.

Antiandrogenic therapy, which inhibits binding of androgen to its receptor, may be added in adolescents in whom hirsutism is the main problem. Antiandrogens including spironolactone, flutamide, finasteride, and cyproterone acetate inhibit the androgen-induced transformation of vellus to terminal hairs. Thus, the effects of these agents usually are not appreciated before 9–12 months because of the long growth cycles of sexual hair follicles. They should be prescribed with an OCP because they may cause menstrual disturbance and their potential teratogenic feminization of the male fetus.

If fertility is an issue, clomiphene citrate with and without metformin is the treatment of choice for ovulation induction.

Cutaneous hirsutism can be treated by cosmetic and dermatologic measures, and/or by medical endocrinologic therapy. Masking the presence of excess hair and physical hair removal are cornerstones to treat hirsutism; shaving, chemical depilatory agents, bleaching, and waxing techniques are effective but can cause skin irritation. Eflornithine hydrochloride cream inhibits hair growth and takes about 6–8 weeks for clinical effect. Laser therapy and electrolysis removes hair permanently by destruction of the dermal papilla.

Gonadotropin-releasing hormone analogs have been prescribed for patients not responding to the above therapeutic agents. GnRH analogs decrease gonadotropin secretions, lower androgen concentrations, lower hirsutism score and hair shaft diameter in patients with PCOS. However, add back therapy needs

to be added to prevent the long term consequences of estrogen deficiency.

### IN A NUTSHELL

1. Menstrual disturbance is the most common gynecological complaint of adolescent girls as the cycles are anovulatory in the first 2 years post menarche.
2. Patients who are pregnant can present with secondary amenorrhea, and rarely primary amenorrhea, irregular or heavy menstrual bleeding and hence, urine pregnancy test should be the first step in evaluating these adolescents, regardless of the stated sexual history.
3. A detailed and systematic work up is essential to find out the cause of primary amenorrhea. Adolescents with Müllerian abnormalities can have children even in the absence of uterus by oocyte retrieval, fertilization of the egg in vitro, and a gestational carrier.
4. In the hypoestrogenic causes of amenorrhea in adolescent, it is important to give estrogen replacement therapy for secondary sexual character development, maintenance and menses and acquisition of normal bone mass.
5. The detection of Y chromosome in the karyotype requires gonadectomy as soon as the diagnosis is made because of the risk of development of neoplasia and the risk of virilization.
6. Menstrual complaints like heavy bleeding and dysmenorrhea are a common cause of limitation of daily activities and school absenteeism, and a cause of anxiety for the patient and their families.
7. Coagulation disorders commonly present for the first time as puberty menorrhagia, therefore, every patient should have a coagulation screen.
8. Polycystic ovary syndrome is the most common endocrinopathy among young adults and is responsible for 70–85% of cases of androgen excess in adolescents.
9. Polycystic ovary syndrome is a syndrome and not a disease. It is characterized by menstrual disturbance, signs of hyperandrogenism, infertility and/or obesity.
10. It is important to recognize PCOS because it has metabolic and cardiovascular risks. Adolescent girls with PCOS are at increased risk for impaired glucose tolerance, type 2 diabetes, dyslipidemia, hypertension and myocardial infarction.

## Chapter 25.6

# Sexually Transmitted Infections

Newton Luiz

Sexually transmitted infections (STIs) occur more frequently in sexually-active adolescents than in adults. They are at least twice as common in girls as in boys and occur earlier in them. The incidence is believed to be on the rise. In 2003, more than 5% of the adult population in India suffered from STIs. There is no reliable data on the incidence of STIs in adolescents in India or other developing countries. In a study done in six representative states in India in 2006-2008, in which 50,848 adolescents and youth aged 15-24 were privately interviewed about their sexual experience by sensitive and trained young personnel, 12% of the males and 3% of the females admitted to premarital sex. In an older 1997 Indian study in adolescents aged 16-17 years, 8% of males and 1% of females admitted that they had experienced sex. In a college study in Nepal in 2006, 35% of adolescent males claimed to have had premarital sex. Adult data on STI in India suggests that chlamydia and gonorrhea are the commonest infections, while syphilis, chancroid and trichomoniasis are also frequent. Infection due to herpes simplex virus (HSV) and human papilloma virus (HPV) are probably under-reported due to lack of awareness.

### PHYSICAL FACTORS AFFECTING GIRLS

- The adolescent vagina is more prone to infection than the adult vagina. Early sexual debut is associated with a high incidence of STIs.
- After puberty, as a result of increasing estrogen levels, the simple columnar epithelium of the adolescent vagina changes over many years into stratified squamous epithelium, thus making it resistant to infection. But throughout adolescence 70% of females continue to have some columnar epithelium at the junction of the vagina with the uterine cervix, a condition called *cervical ectopy* that predisposes to cervical infection.
- The hormonal changes of puberty increase local mucus production and decrease the pH. This decreases susceptibility to chlamydia and gonorrhea but increases susceptibility to *Candida albicans* and *Trichomonas vaginalis*.
- The smaller introitus of the adolescent girl predisposes her to physical trauma during coitus.

### OTHER FACTORS

- Infection is usually asymptomatic in adolescents.
- There is low awareness about STI among adolescents. Education about STI is meager in the school syllabus, and a significant percentage of adolescents do not attend high school. Girls are often unable to differentiate normal from abnormal vaginal discharge.
- The sexually active girl is more concerned about the possibility of pregnancy or menstrual problems than STIs.
- Adolescents have inadequate concern about their future health, and indeed believe that they are physically invulnerable. A risk-taking attitude is common at this age.
- Even when concerned, adolescents have difficulty accessing sexual advice. There may be no special facilities for adolescents or they may be unaware of the facilities available. The facilities may be far away from home and school or may not be available outside school hours. Adolescents may not have the financial resources to visit a hospital, to do tests and to buy medicines.

The girl dislikes pelvic examinations and is reluctant to discuss her complaints if the doctor is a male. The boy is too embarrassed to ask about condoms.

- Adolescents fear disapproval of their sexual behavior. They worry that their parents or friends may come to know of their problem.
- The adolescent may be a victim of sexual abuse.

### MAJOR INFECTIONS

#### HIV/AIDS

This major STI presents predominantly with systemic rather than genital lesions and is discussed in detail in another chapter.

#### Gonorrhea

This is caused by *Neisseria gonorrhoeae*, a gram-negative intracellular diplococcus. Genital infection is symptomatic in 90% of infected men but only 20% of infected women. The incubation period is 2-5 days. It presents as urethritis in boys; if untreated, a urethra abscess or stricture may develop. In girls, it causes cervicitis and is a major cause of pelvic inflammatory disease (PID). About 20% of boys and 40% of girls with gonorrhea have associated chlamydial infection. A single dose of oral cefixime 400 mg is effective against gonorrhea. A single dose of injectable ceftriaxone 250 mg intramuscular (IM) is preferred and has the extra benefit of being effective against incubating syphilis and chancroid (but not against *Chlamydia*).

#### Chlamydia

This is the commonest of the STIs, but the majority of affected adult women is asymptomatic or only has a mucoid vaginal discharge. It often causes silent PID. It is more common and more severe in adolescents: 20% of adolescent girls with *Chlamydia trachomatis* infection will suffer from chronic pelvic pain, 10% will have an ectopic (tubal) pregnancy in the future and 20% will become infertile. Women with *C. trachomatis* infection have a four-fold increased risk for acquiring HIV infection. Asymptomatic urethral infection is common in men, but it is the commonest cause of nongonococcal urethritis (NGU) and is a major cause of epididymitis. Diagnostic tests are costly and unreliable. A single dose of azithromycin 1 g is effective; so is doxycycline 100 mg BD  $\times$  7 days.

#### Genital Herpes

It is characterized by multiple painful shallow ulcers that heal spontaneously within weeks, but more than 50% have lifelong intermittent episodes of viral shedding. It can also cause cervical ulcers. HSV-2 is the usual cause, while HSV-1 is an infrequent agent.

#### Chancroid

This is caused by *Haemophilus ducreyi*, a gram-negative coccobacillus. A papule occurs within a week of exposure and rapidly ulcerates. Without treatment the ulcer may last for weeks or months. There is unilateral tender inguinal lymphadenitis which may become fluctuant and a discharging sinus may develop. Effective regimens include ceftriaxone 250 mg IM stat, azithromycin 1 g orally stat, erythromycin 500 mg QID  $\times$  7 days or ciprofloxacin 500 mg BD  $\times$  3 days.

#### Syphilis

This great scourge of the past is now rare in developed countries, possibly because it is usually symptomatic and can be diagnosed by simple tests. But primary syphilis, an indolent infection caused by *Treponema pallidum* that presents as a genital ulcer, is not uncommon in developing countries. Secondary and late syphilis do not cause genital ulcers and are infrequent in adolescence.

## Trichomoniasis

*Trichomonas vaginalis* is a flagellated protozoan parasite that primarily causes vulvovaginitis in girls but infrequently causes PID in women and chronic prostatitis in men. Most men and up to 30% of women are asymptomatic.

## Lymphogranuloma Venereum

This disorder is caused by *C. trachomatis* (L1, L2 and L3 serovars). The characteristic feature is femoral or inguinal lymphadenitis with enlarging, painful buboes that break down to form multiple draining sinuses. As the disease progresses, the patient suffers from rectovaginal fistulas, rectal strictures and urethral damage. Doxycycline 100 mg BD  $\times$  21 days is the recommended treatment. Azithromycin 1 g weekly for 3 weeks is an effective alternative.

## Granuloma Inguinale (Donovanosis)

This STI is caused by *Klebsiella granulomatis* (formerly called *Calymmatobacterium granulomatis*). As it heals very slowly, treatment should be given for 3 weeks or until all lesions heal, whichever is longer. Thus, treatment requires doxycycline 100 mg BD  $\times$  21 days. Alternatives include azithromycin 1 g weekly or ciprofloxacin 750 mg BD for 3 weeks.

## Bacterial Vaginosis

This is very common. It is not a STI but is often mistaken for one. It occurs when *Lactobacillus*, which is the normal vaginal flora of the vagina, is replaced by an overgrowth of *Mobiluncus* (an anaerobe), often in association with *Gardnerella vaginalis*, *Ureaplasma urealyticum* and *Mycoplasma genitalium*.

## Candidiasis

Candidal vulvovaginitis is more common in adolescents who use oral contraceptives, after oral antibiotic therapy or when pregnant. There is vulvar pain or itching, dysuria, vulvar or vaginal erythema and an opaque white or cheesy exudate. A single dose of fluconazole is effective.

## DIAGNOSIS

Many STIs are curable and all are treatable. But the majority of STIs are asymptomatic and when symptomatic, the manifestations are variable and usually nonspecific. Hence, a syndromic approach to management is preferred in resource-poor settings, where the laboratory facilities and expertise required for diagnosis are either limited or unavailable or unaffordable. Case management goes beyond history taking, clinical examination, diagnosis and prompt management, and includes partner management, counseling to prevent recurrence and careful follow-up.

## History Taking

Adolescents are naturally anxious about visiting a clinic. This stress can be alleviated if the clinic has a bright, attractive waiting room with magazines that would attract adolescents, and/or a TV showing programs of interest to adolescents. Both male and female staff should be present, and should be friendly and patient. The consulting room should offer privacy for genital examination and one should ensure that conversations cannot be overheard. Adolescents should not be expected to visit an *STI Clinic*. The clinician should emphasize confidentiality right at the start. He should be nonjudgmental and reassuring even when he suspects the adolescent's honesty. Most adolescents are not frank or open initially and it may take time to gain their confidence. One should expect the adolescent to be unwilling or embarrassed to share information. A high degree of suspicion is required, as the

adolescent may only mention lesser or nonspecific complaints and hope that the clinician will find the right diagnosis.

History taking will initially focus on the presenting complaints. Next one should ask leading questions about symptoms that could possibly be due to an STI. Does the girl have normal and regular menstrual cycles, dysmenorrhea, dysuria or frequency micturition, vaginal discharge (and if so what is the amount, odor, color); does she have genital itch or rash or ulcers? Does the boy have dysuria or frequency of micturition, discharge of pus from the penis, genital itch or rash or ulcers, scrotal pain or swelling, or groin swelling? Have these symptoms occurred in the past and if so, was any treatment taken?

Finally one should take a sexual history. Is the adolescent having sex, and if so how often; is it with a person of the opposite or same sex; is it genital, oral or anal sex? Has he or she had sex earlier and with how many partners? Has the adolescent ever been tested for, diagnosed with or treated for STI? What about the partner? Is any protection against pregnancy or STI used, and if so what and how regularly?

## Clinical Examination

Before doing a genital examination, the clinician should explain what is to be done and why. If the patient is below 18 years, parental permission is needed. Ask the adolescents if they wish someone trusted to be present. If examining a member of the opposite sex, an assistant of the same sex as the patient should be present.

Start with a general examination including the vital signs, inspection of the skin and mucous membranes. Do a systematic search for enlarged lymph nodes and record their size, consistency, number and whether tender.

Use gloves during genital examination. When examining the male adolescent, look for penile rashes or ulcers. Retract the foreskin and systematically examine the glans penis, coronal sulcus, frenum and urethral meatus. If there is no obvious discharge, milk the urethra 3-4 times from the base toward the urethral meatus. Palpate the testis, epididymis and spermatic cord.

In the female, separate the labia majora with both hands and inspect the labia majora and minora, the Bartholin glands and the introitus. Pressing under the urethra with one finger might cause a drop of urethral discharge to come out. Holding the labia majora apart and pulling them toward the examiner permits internal examination. Palpate the abdomen, looking for a mass or pelvic tenderness. Separate the buttocks with two hands to visualize the area properly. Do a rectal examination and proctoscopy if there is rectal discharge or history of anal intercourse.

## Investigations

- All symptomatic patients should be tested for chlamydia and gonorrhea if possible, and an HIV rapid test, venereal disease research laboratory test (VDRL) and hepatitis B surface antigen (HBsAg) should be done
- Pregnancy test should be done to all with suspected PID as management differs, if pregnant
- Repeat tests after 3 months to confirm cure in chlamydia and gonorrhea
- Partners should be tested, if possible.

## Vaginal Discharge

Vaginal fluid is collected with a swab inserted deep into the lateral or posterior fornices of the vagina, or from the tip of the speculum after a speculum examination of the vagina. The use of jelly or disinfectant will interfere with the results. The tests described below will give us a diagnosis in up to 80% of cases of vaginal discharge.

## pH

Using pH paper of range 3.8–6.0, one can check the pH of the vaginal fluid. It is normally 4.0 and is usually more than 4.5 in bacterial vaginosis (BV) and trichomoniasis. A negative pH test makes a diagnosis of BV very unlikely, but a positive test may be due to *Trichomonas* or contamination with cervical mucus, semen or menstrual blood.

## Saline Microscopy

A fresh sample may reveal the darting motility of *Trichomonas* in 80% of symptomatic girls (but only 50% of asymptomatic girls), the yeast cells of *Candida* or the presence of *clue cells* in BV. Clue cells are epithelial cells that are covered with many small coccobacilli making their edges indistinct. Plenty of WBCs are seen in PID. The vaginal discharge has a foul odor in BV and if a drop of 10% KOH is added, the slide immediately emits a fishy odor. 70% of cases of candidiasis can be diagnosed by adding KOH which dissolves the other cells and makes the yeast cells and pseudohyphae more obvious.

## Gram Stain

In BV, the lactobacilli are replaced by a variety of other microbes; clue cells are seen more clearly than in saline microscopy. In gonorrhea, there may be WBCs with intracellular gram-negative diplococci. Though the yield is good in urethral pus, it is low in vaginal discharge and vaginal commensals often produce a similar picture. Culture usually grows only commensals.

## Urethral Discharge in Men

In gonorrhea, Gram stain will reveal WBCs with intracellular gram-negative diplococci. In NGU, there will be more than five neutrophils per oil immersion field and a first-void (NOT midstream) urine sample will show more than 10 neutrophils per high power field.

## Genital Ulcers

Rapid plasma reagin (RPR) and VDRL are excellent nontreponemal screening tests that pick up most cases of early syphilis, but occasional false positives are seen. Treponema pallidum hemagglutination test (TPHA) is a confirmatory test. In chancroid, *H. ducreyi* may be picked up by a Gram stain or culture. The Tzanck test is insensitive and not specific for HSV.

## Other Tests

Pelvic inflammatory disease can be diagnosed by a USG and more accurately by MRI or a laparoscopy, which will reveal thickened, fluid-filled tubes with or without free pelvic fluid, or a tubo-ovarian mass and help to rule out other causes of abdominal pain. HSV can be diagnosed by serology, PCR and culture, but these tests are costly and not easily available and have limited accuracy. Nucleic acid amplification tests (NAATs) are the most sensitive tests for chlamydia and gonorrhea and allow testing on self-collected vaginal swabs, or less sensitively on urine. They are costly and not easily available.

## PRINCIPLES OF TREATMENT AND COUNSELING

- The drug used should preferably be at least 95% effective, low-cost, single-dose, oral, with low toxicity and not contraindicated in pregnancy.
- One should explain to the patient how he got the infection and how it can be cured so that he understands why drugs are needed and how to avoid getting infected in future and how to prevent infection from spreading to others.
- The importance of treating the sex partner should be emphasized.

- The patient and partner should practice sexual abstinence until 7 days after completing treatment.
- There should be a return visit after 7 days to ensure treatment compliance, to see the reports of tests done and to confirm cure.
- Counseling should be tailored to the adolescent's unique life situation. It is important whenever possible to help the patients develop critical thinking skills, promote their self-esteem and encourage positive values.

## SYNDROMIC APPROACH TO SEXUALLY TRANSMITTED INFECTION

### Urethral Discharge or Burning Micturition in Boys

Urinary tract infection in an adolescent boy is due to an STI until proved otherwise. This is usually gonorrhea which presents as a mucopurulent urethral discharge. NGU is caused by *Chlamydia* in up to 50% of cases; the etiology is unknown in the rest, though *Trichomonas*, *M. genitalium* and *U. urealyticum* are sometimes implicated.

### Treatment

Treatment should cover both gonorrhea and chlamydia as dual infection is common:

- Ceftriaxone 250 mg IM (for *N. gonorrhoeae*) + oral azithromycin 1 g stat (for *Chlamydia*)
- If allergic to azithromycin, give erythromycin 500 mg QID × 7 days (50 mg/kg if <40 kg)
- If symptoms persist or recur, treat for *Trichomonas* with metronidazole 2 g stat orally.

### Scrotal Pain or Swelling

Both *Chlamydia* and the gonococcus can cause epididymo-orchitis which manifests as acute scrotal pain and swelling. Examination reveals a swollen and tender epididymis and testis, and there may be hydrocele and urethral discharge. Fever and malaise are present, and there may be associated dysuria. As orchitis can reduce fertility, it should be treated aggressively for both gonococcal and chlamydial infection.

### Treatment

Treatment consists of cefixime 400 mg BD × 7 days and doxycycline 100 mg BD × 14 days (2.2 mg/kg/day if <45 kg). Other causes of acute epididymo-orchitis include mumps, filaria and infection by coliform bacteria. Torsion of the testis is an important differential diagnosis.

### Inguinal Bubo

Chronic inguinal lymphadenitis (buboes) caused by STIs tend to break down and leave draining sinuses.

Lymphogranuloma venereum (LGV) starts with small painless papules on the external genitalia. Later the characteristic buboes appear which break down to form multiple fistulae. If untreated, the patient may develop lymphatic obstruction resulting in elephantiasis of the lower limbs or genitals. Granuloma inguinale (Donovanosis) presents with painless buboes that break down to form beefy red painless ulcers. Chancroid usually presents more acutely and has a single draining sinus.

### Treatment

Doxycycline 100 mg BD × 21 days at least (for LGV and Donovanosis) and azithromycin 1 g stat (for chancroid). Avoid local incision and drainage as this leads to chronic sinus formation. If fluctuant, aspirate.

The differential diagnosis includes local bacterial infections of the genitalia, groin, perineum, buttocks and lower limbs that can involve the inguinal glands and also chronic involvement due to *Mycobacterium tuberculosis* or filariasis.

### Genital Ulcers

Herpes simplex virus, syphilis and chancroid are the usual causes of penile and vulvar ulcers. Genital herpes is characterized by multiple vesicles or painful shallow ulcers. Acyclovir 400 mg TID  $\times$  7 days may be given. Chancroid presents with multiple painful ulcers with nonindurated and undermined borders and a purulent base. A painful bubo is occasionally seen. Primary syphilis manifests as a chancre, i.e., a single painless ulcer on the labia majora or penis with a well-demarcated indurated border and a clean base. The lymph nodes are enlarged, rubbery and nontender.

### Treatment

Benzathine penicillin 50,000 IU/kg (up to 2.4 million units) deep IM stat (for syphilis), given in two divided doses as the volume for injection is large and azithromycin 1 g stat orally (for chancroid). If allergic to penicillin, give doxycycline 100 mg BD  $\times$  14 days.

### Vaginal Discharge

Vaginitis in adolescence is usually due to BV, but *Trichomonas* and *Candida* can cause vaginitis. Cervicitis, caused by *N. gonorrhoeae*, *Chlamydia*, *Trichomonas* and HSV can result in a profuse cervical discharge which manifests externally as vaginal discharge. A speculum examination will differentiate between the two, but if the adolescent refuses one will need to treat for both. It is essential to rule out PID.

In BV, there is no vulvar itch or soreness. The vaginal discharge is sticky, grayish in color and has a foul odor. Gonorrhea presents with a vulvar itch, mild vaginal discharge, urethritis or cervicitis. Chlamydial cervicitis produces a red friable cervix which manifests with intermenstrual or postcoital bleeding, or a profuse mucopurulent discharge. Trichomoniasis causes a malodorous frothy yellow-green vaginal discharge with vulvar soreness and irritation. Candidiasis causes vulvar pruritus, pain, redness and excoriation, and a thick curdy white discharge. Candidal vaginitis increases during menstruation. HSV rarely causes an ulcerative cervicitis.

### Treatment

If vaginitis is diagnosed, give metronidazole 2 g stat orally (for BV and *Trichomonas*) and fluconazole 150 mg stat or clotrimazole 500 mg intravaginally as a single dose (for *Candida*). If cervicitis is suspected, give ceftriaxone 250 mg IM (for *N. gonorrhoeae*) and azithromycin 1 g stat (for *Chlamydia*).

### Lower Abdominal Pain

Lower abdominal pain in girls may indicate PID. It is rare for the infection to be sharply localized, especially in adolescent girls. An ascending infection of the internal genitalia can affect the uterus, fallopian tubes, ovaries, the pelvic peritoneum, the vascular tissues and/or connective tissue. There may be endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. The infecting agent is usually gonococcus or *Chlamydia*; other causes include anaerobes like *Mobiluncus*, *Gardnerella*, enteric gram-negative bacilli, *M. genitalium* and *U. urealyticum*.

Pelvic inflammatory disease may be asymptomatic (silent PID), especially in chlamydial infection, or it may present with chronic pelvic pain. There may be vaginal discharge, menorrhagia, dysmenorrhea, dyspareunia, dysuria, tenesmus or low backache. On examination, some girls have high fever, tenderness and guarding of the lower abdomen, a pelvic mass, or tenderness of the adnexa or cervical motion. The erythrocyte sedimentation rate

(ESR) is raised. The differential diagnosis includes twisted ovarian cyst, ovarian tumor, endometriosis, ectopic pregnancy, threatened or septic abortion, tubo-ovarian abscess, UTI and gastrointestinal tract (GI) disorders like appendicitis and inflammatory bowel disease.

### Treatment

Treatment consists of cefixime 400 mg BD  $\times$  7 days and doxycycline 100 mg BD  $\times$  14 days and metronidazole 400 mg BD  $\times$  10 days. Careful follow-up is essential to confirm cure.

### Genital Skin Lesions

Human papilloma virus causes genital warts (condyloma acuminata) which consist of multiple soft painless pink cauliflower-shaped growths on the external genitalia, around the anus or in the perineum. Apply 20% podophyllin on the wart and wash it off after 3 hours. The surrounding areas should be protected with vaseline before applying it. Do this weekly till the lesions resolve. Cervical lesions cannot be treated with podophyllin, and cryotherapy is needed. Other causes of warts are HPV-6 and HPV-11 (which cause benign genital warts), molluscum contagiosum and syphilis (which cause condylomata lata).

### Oral and Anal Sexually Transmitted Infections

A high degree of suspicion is required to diagnose them. There is a history of oral or anal sex. Orally, there may be ulcers or pharyngeal inflammation. Anal STI can cause anal discharge, tenesmus, diarrhea, blood in stool, abdominal cramps and local ulcers or vesicles. *N. gonorrhoeae*, *Chlamydia*, HSV, *T. pallidum* and *H. ducreyi* are the usual agents.

### Sexually Transmitted Infection and Pregnancy

Adolescents are more likely when pregnant to have a miscarriage than adult women and this is partly due to their higher incidence of STIs.

### PARTNER THERAPY

Partner therapy is important to cure the partner (who may be asymptomatic and so does not seek treatment), to prevent the primary patient from being reinfected and to prevent other persons from being infected by the partner. The patient should be convinced of the importance of partner management and he or she should be asked to bring the partner along. Both of them should be treated for any STIs found in either of them. If it is not possible to examine the partner, a prescription is given for empirical treatment of the partner without evaluation and this is known as *expedited partner therapy*.

There is always a risk of wrongly labeling a patient as having a STI as the symptoms of many STIs are nonspecific, e.g., vaginal discharge. The result is that one unnecessarily treats the sexual partner. Nevertheless, when one suspects PID, the danger of undertreatment is greater and it better to counsel them that there is an infection that could possibly reduce fertility if untreated and advise both to take treatment.

### PREVENTION

#### Educate the Adolescent about Sexually Transmitted Infections

This is most practical in schools. Where school enrolment is low other sources of information could be youth clubs, youth magazines, libraries and churches. The importance of this was emphasized by a cross-sectional survey in 2006-2007 of urban girls studying in the 11th and 12th grades in Delhi: 53% had never

attended a class on STI, HIV or safe sex; 22% agreed that premarital sex was acceptable between loving couples; 30% believed that HIV was curable and 44% had not heard of gonorrhea.

### Make Available Adolescent Friendly Health Services

Early diagnosis and treatment will prevent further spread of disease. These services should be exclusive to adolescents, should be open soon after or before school hours and should be situated close to schools. They should preferably offer multiple activities such as evening classes and sports facilities so that the adolescent who wishes to visit them can do so without drawing attention to himself or herself. *Do routine screening* to detect cases early. This implies a sexual history that is appropriate to the adolescent's developmental level and culture.

### Routine Screening Tests

While simple low-cost screening tests are available for HIV and syphilis, they are not available for common organisms like *Chlamydia* and *gonorrhoeae*. All patients who come in with complaints suggestive of STI, or are found to have STI, should be routinely tested for HIV and syphilis. Ideally, all sexually active adolescents should be screened confidentially for chlamydia and gonorrhea every year.

### Promote Condom Use among Sexually Active Adolescents

Condoms are highly effective for prevention of HIV and quite effective for the other STIs, though less so for genital ulcers and HPV. Ignorance about condoms, nonuse, wrong use and repeated use of the same condom are all common. Many adolescents believe that if they are in a regular relationship with a single partner the risk of STI is negligible, yet US data shows that 19.7% of adolescents with STI had only one sex partner.

### Immunization

Human papilloma virus is vaccine preventable in theory. The vaccines available have 70% efficacy in American whites, but their efficacy is lower in American blacks and their efficacy in Asian populations is unknown. There is also inadequate data on what percentage of the population is already seropositive at any given age. Hepatitis B can be transmitted as a STI and hepatitis B vaccine is highly effective when given at 0, 1 and 6 months.

### GOVERNMENT PROGRAMS TO CONTROL SEXUALLY TRANSMITTED INFECTIONS

The prevention, management and control of STIs are mainly under the Reproductive Child Health-II (RCH-II) program. The National AIDS Control Program-III (NACP-III) includes STI management services as a major program for prevention of HIV. It aims to provide services to the general population and simultaneously to focus on certain high risk behavior groups. The main objectives are to: enhance access to services, especially for adolescents and to high-risk groups; standardize treatment protocols and emphasize

treatment compliance; focus on prevention including partner management and condom use; bring about behavior change by enhancing knowledge; and provide counseling and testing services for HIV or AIDS.

#### IN A NUTSHELL

1. STIs are common in sexually active adolescents, especially in females.
2. They are often asymptomatic, yet cause considerable immediate and long-term morbidity and also predispose the adolescents to HIV.
3. STIs are more common in adolescents than in adults due to genital immaturity in girls, low awareness of STI, poor access to health services, inadequate concern for their health and the normal risk-taking attitude of this age.
4. The common causes are *C. trachomatis*, *N. gonococcus*, HSV, *Trichomonas*, HPV, *H. ducreyi* and *T. pallidum*. Multiple infections are common.
5. The usual presentations are urethral discharge, scrotal pain and swelling, inguinal bubo, genital ulcer, vaginal discharge or low abdominal pain.
6. A syndromic approach to management is preferred as sensitive low-cost diagnostic tools are not available.
7. The drugs used should preferably be at least 95% effective, low-cost, single-dose, oral, with low toxicity and not contraindicated in pregnancy.
8. Case management should include treatment of the patient and partner, counseling to prevent recurrence and careful follow-up.
9. There is a need for adolescent friendly, accessible, low-cost health facilities.
10. There is an urgent need for providing Family Life Education to adolescents including awareness of STI and HIV.

## Chapter 25.7

# Teenage Pregnancy

Amita Suneja, Richa Aggarwal

Teenage pregnancy is high risk pregnancy with medical and social problems. It is of concern to pediatric health care givers during discussions of sexual activity, contraception or during diagnostic evaluation of problems such as menstrual irregularities, gastrointestinal complaints or pelvic mass.

In developed countries, teenage pregnancies are often associated with social issues including lower educational levels, poverty and other poor life outcomes in children of teenage mothers. Teenage pregnancy in developed countries is usually outside of marriage and carries a social stigma in many communities and cultures.

By contrast, teenage parents in developing countries are often married and their pregnancies welcomed by family and society. However, in these societies, early pregnancy may combine with malnutrition and poor health care to cause medical problems.

## MAGNITUDE OF THE PROBLEM

About 16 million girls aged 15-19 years and 2 million girls under the age of 15 give birth every year. Worldwide, one in five girls has given birth by the age of 18. In the poor regions of the world, this figure rises to over one in three girls. Pakistan and Sri Lanka show much lower rates of pregnancies among women aged 15-19 than India and Bangladesh according to the report titled *Motherhood in Childhood*. For every 1,000 girls aged 15-19, there were 76 adolescent births in India in 2010 compared to 49 worldwide and 53 in less developed regions.

## FACTORS CONTRIBUTING TO TEENAGE PREGNANCY

### Early Marriage

India and Bangladesh remain among the countries where a girl is extremely likely to be married before she is 18 and have a child while still a teenager. The expectation in the sociocultural milieu that after marriage a woman will become pregnant as soon as possible encourages early onset of maternity.

### Poverty

Almost all adolescent births—about 95% occur in low- and middle-income countries. Within countries, adolescent births are more likely to occur among poor, less educated and rural populations. At least one-third of teenagers who become pregnant are themselves product of teenage pregnancy.

### Early Puberty

The average age of menarche is decreasing and as a result of early menarche and changing sexual pattern, a marked increase in the number of young pregnant girls has been witnessed. The youngest mother reported in literature is Lina Medina who was around 5 years old when she was delivered by cesarean section in Lima, Peru in 1939.

## Increasing Sexual Activity among Teenagers

The increased sexual activity among adolescents is manifested as increased teenage pregnancies and an increase in sexually transmitted diseases. In a 2005, Kaiser Family Foundation study of

US teenagers, 29% of teens reported feeling pressure to have sex, 33% of sexually active teens reported *being in a relationship where they felt things were moving too fast sexually*, and 24% had *done something sexual they didn't really want to do*. Several polls have indicated peer pressure as a factor in encouraging both girls and boys to have sex. Younger teenagers are especially vulnerable to coercive and nonconsensual sex.

## Childhood Sexual Abuse

Subsequent teenage pregnancy in industrialized countries up to 70% of women who gave birth in their teens were molested as young girls; by contrast, 25% of women who did not give birth as teens were molested.

## Lack of Contraception

Adolescents may lack knowledge of or access to conventional methods of preventing pregnancy as they may be too embarrassed or frightened to seek such information. Contraception for teenagers presents a huge challenge for the clinician. Young women often think of contraception either as *the pill* or condoms and have little knowledge about other methods. They are heavily influenced by negative, second-hand stories about methods of contraception from their friends and the media. Prejudices are extremely difficult to overcome. Over concern about side-effects, for example weight gain and acne, often affect choice. Missing up to three pills a month is common, and in this age group the figure is likely to be higher. Restarting after the pill-free week, having to hide pills, drug interactions and difficulty getting repeat prescriptions can all lead to method failure.

In other cases, contraception is used but proves to be inadequate. Inexperienced adolescents may use condoms incorrectly, forget to take oral contraceptives or fail to use the contraceptives they had previously chosen. Contraceptive failure rates are higher for teenagers, long-acting contraceptives, such as intrauterine devices, subcutaneous contraceptive implants and contraceptive injections (such as Depo-Provera and combined injectable contraceptive), which prevent pregnancy for months or years at a time are more effective in women who have trouble remembering to take pills or using barrier methods consistently.

According to The Encyclopedia of Women's Health, published in 2004, there has been an increased effort to provide contraception to adolescents via family planning services and school-based health such as HIV prevention education.

## RISKS OF TEENAGE PREGNANCY

Teenage pregnancy is primarily a sociological problem with medical consequences. Rather than maternal age itself as the sole factor, the obstetric risks for older teenagers are more related to poverty, inadequate nutrition, poor health before pregnancy, unmarried status and poor education and lack of antenatal care. The common problems are listed in **Box 1**.

## PREVENTION

WHO published guidelines on how to prevent early pregnancies and poor reproductive outcomes among adolescents in low- and middle-income countries. These include legalization of minimum age for marriage, creating understanding and support to reduce pregnancy before the age of 20, introducing sex education in schools, increasing the use of contraception by adolescents at risk of unintended pregnancy, reducing coerced sex among adolescents, reducing unsafe abortion among adolescents and increasing the use of skilled antenatal, childbirth and postnatal care among adolescents.

**BOX 1 Problems of teenage pregnancy**

- *Increased maternal morbidity and mortality due to:*
  - More likelihood of unsafe abortions
  - Less likely than adults to obtain skilled care before, during and after childbirth
  - Pregnancy related complications: preterm labor, pre-eclampsia, anemia
  - Teenagers are more likely to have sexually transmitted infections (STIs): chlamydia, syphilis and HIV
  - Teenagers are more likely to smoke and take drugs: placental problems
  - More complications of childbirth due to fetopelvic disproportion
- *Fetal risk*
  - Low birth weight (LBW) babies
  - Still births, newborn and infant deaths: Stillbirths and newborn deaths are 50% higher among infants born to adolescent mothers than among those born to mothers aged 20–29 years
  - Fetal effects because of STI and substance abuse: LBW, sudden infant death syndrome
- *Other consequences*
  - Dropouts from school
  - Lack of job skills
  - Financial dependence

**MORE ON THIS TOPIC**

WHO. Adolescent Pregnancy. Fact sheet. Geneva: WHO; 2012. From: [www.who.int/mediacentre/factsheets/fs364/en/](http://www.who.int/mediacentre/factsheets/fs364/en/). Accessed November 5, 2008.

**IN A NUTSHELL**

1. Teenage pregnancy is high-risk pregnancy with medical and social problems.
2. In developing countries, practice of early marriage while in developed countries, liberal society and early initiation of sexual activity are major contributing factors for teenage pregnancy.
3. Teenage pregnancy is associated with increased perinatal and maternal morbidity and mortality.
4. To prevent teenage pregnancies, sex education, easy availability of contraceptives and strict enforcement of law for minimum age of marriage are essential.

# Section 26 CARE OF ADOLESCENTS

**Section Editor** MKC Nair

## Chapter 26.1

### Promoting Health of Adolescents

*Harish K Pemde, Kamlesh Harish*

Youth (10–24 years) are nearly one-third of India's population and adolescents (10–19 years) constitute over one-fifth of India's population, i.e., 253 million. Social and economic fortunes of this country depend heavily on the health and well-being of this population. We need to leverage this demographic advantage to the benefits of country and its people. We need to invest in promotion of health of adolescents to achieve India's health goals including country targets for Millennium Development Goals. A large number of adolescents face many challenges in healthy development and transition to adult life. A variety of factors influence this transition and these include structural poverty, inadequate school education, negative social norms, early marriage and child bearing, and social discrimination. To respond to these factors we need to view adolescence in a life span perspective within dynamic sociological, cultural and economic realities. Thus, sectors like education, social justice, youth empowerment, sports and legislation need to join health sector in promoting health of adolescents. Pediatricians are placed uniquely in this system and they are expected to make a delicate balance between these sectors for promoting health of adolescent client(s). This chapter describes principles of promotion of health of adolescents, risk and protective factors, prevention interventions including life skills education, family life education (FLE), adolescent education program (AEP) and adolescent vaccination.

#### ELEMENTS OF HEALTHY DEVELOPMENT

Adolescence is a critical phase of the life of an individual as achievements and deficiencies during this phase determine, to a large extent, the future adult life. The achievements in social functioning, personal interactions and relationships, and health-care are interrelated and go together. Health is influenced by all these factors. What matters the most is healthy development of an adolescent. Following eight elements have been identified as fundamental requirements for healthy development of adolescents:

1. Participate as citizen, household member, worker, and as responsible member of society
2. Gain experience in decision making
3. Interact with peers, and acquire a sense of belonging
4. Reflect on self in relation with others, and to discover self by looking outward as well as inward
5. Discuss conflicting values and formulate one's own value system

6. Experiment with one's own identity, with relationship to other people, and with ideas to try out various roles without having to commit oneself irrevocably
7. Develop a feeling of accountability in the context of a relationship among equals
8. Cultivate a capacity to enjoy life.

The family, society, government and medical practitioners have to incorporate these elements of adolescent development for prevention and reduction of specific risk behaviors such as substance use, violence, physical inactivity, unhealthy diets, and unprotected sex and its consequences.

#### GENERAL HEALTH SCREENING

Adolescence is a stage of life where individuals remain more or less healthy. But, one should never forget that certain behaviors like smoking or inadequate physical exercise very often begin during this period which can lead to ill health during adult life. Some adolescents may carry some risk factors too which if left unattended may lead to diseases after few years when they become adults.

Screening adolescents for risk factors is important and is different than that in adult as in adults we look for existing diseases but in adolescents we look for risk factors in addition to existing conditions.

#### Identification of the Risk Factors in Adolescents

This is of paramount importance that we look for risk factors in adolescence in our clinical encounters with them. If one or more risk factors are found then *selective screening* by some blood tests can be added to clinical screening.

#### History

Include some questions related to unhealthy diet, physical activity or inactivity, smoking and substance (including tobacco and alcohol) use/misuse in your history. Ask for family history of diabetes, hypertension, coronary heart diseases, stroke or early (< 45 years of age) death or disability due to acquired heart disease or stroke in parents or grandparents. Some questions are given below:

1. Do you exercise or participate in outdoor games at least 5 days a week?
2. Do you watch television (TV)/computer or spend time on mobile for more than 2 hours per day?
3. Do you consume fruits, fruit juices or green leafy vegetables in your routine diet at least 5 days a week?
4. Does anybody in your family (parents, siblings, grandparents or maternal grandparents, etc.) have high blood pressure, diabetes or any heart disease?
5. Do you consume any kind of tobacco (bidi, cigarette, hookah, gutkha, etc.)?
6. Do you consume any kind of alcohol (beer, whiskey, vodka, etc.) or drugs (*ganja*, *charas*, etc.)?

### Physical Examination

Perform a thorough physical examination including assessment of weight and body mass index (BMI), blood pressure, and systemic examination. Find whether unhealthy diets, overweight or obesity, hypertension, inadequate physical activity or sedentary behaviors are present. Adolescents having one or more risk factors should be considered for targeted screening blood tests. Clear guidelines are not available for adolescents; however, whenever one or more risk factors are identified especially family history as above then in such cases screening for risk factors for atherosclerosis may be advised. Serum cholesterol and very low-density lipoprotein estimation along with fasting blood sugar level should be done. Some studies have used hemoglobin A<sub>1c</sub> (HbA<sub>1c</sub>) as screening for diabetes. Other tests may be required depending on the history and examination of an individual adolescent.

### Adolescent Immunization

Vaccines and immunizations are regarded as one of the most successful public health promoting interventions. Vaccines have saved millions of lives and have resulted in elimination of polio after eradication of smallpox. Vaccines are traditionally used in young children and children up to 5 years of age are the focus of national immunization program. Adolescents do need vaccines for certain reasons. Certain vaccines (e.g., pertussis) do not provide long-term immunity and protection provided by childhood vaccines wane by adolescence. Reinforcement is needed for these diseases including diphtheria, pertussis and tetanus. Adolescents have increased risk of acquiring some new infections in this age. Human papillomavirus is one such infection. Some adolescents might have not developed adequate immunity against certain infections (e.g., hepatitis A or B, chicken pox, mumps and rubella). Adolescents may find themselves in certain new situations promoting some infectious diseases like living in dormitories promote spread of meningococcal infections and hence they need to be protected against these infections. Some adolescents might have missed one or other childhood vaccines or some vaccines were probably not available during their childhood. Catch-up vaccinations are needed for such adolescents. Some students travel abroad and this necessitates administration of certain vaccines as required by travelers. Indian Academy of Pediatrics (IAP) recommendations for vaccination of adolescents are given in **Table 1**.

### Other Vaccines

Pneumococcal conjugate vaccine or pneumococcal polysaccharide vaccine can be given in special circumstances like immune compromised status [human immunodeficiency virus (HIV), etc.], preparing for splenectomy or functional or anatomical asplenia, cochlear implant or cerebrospinal fluid leak. Single dose of either

vaccine is needed. Polysaccharide vaccine can be repeated every 3 years. *Haemophilus influenzae* type b (Hib) vaccine may also be given while preparing for splenectomy.

### LIFE SKILLS EDUCATION

In today's world information is readily available to all including adolescents. However, it becomes more important to learn how to manage this for adolescent whose brains are still maturing and they have a limited capacity to perceive consequences of current acts. The adolescents need skills to use the vast information in their benefit to remain healthy. Out of several life skills the following skills are more important—self-awareness, critical thinking, empathy, coping with stress and emotions, and interpersonal relationship and effective communication. Principles of life skills include the following:

- That, certain life skills are inherently present in all individuals and we need to recognize and to practice to polish them
- That, life skills can be learned and be mastered
- That, life skills are for self
- That, self-awareness is mother of all life skills so one should know his/her strengths and weaknesses
- That, life skills are interdependent, they assist each other, they often work in pairs and are used in combinations
- That, life skills can be used both positively and negatively
- That, in a similar situation different people would use different combinations of life skills
- That, one need to learn and practice them to acquire the life skills
- That, life skills are not the solution of any problem but one of the ways to tackle the problem
- That, life skills are better learned by *learning by doing*; mere talking about life skills is not beneficial.

### Core Life Skills

The World Health Organization (WHO) has identified ten core life skills for adolescents. These skills can be taught to adolescents using various methods like discussion, brainstorming, demonstration and guided practice, role plays, small group discussion, educational games and simulations, case studies, storytelling, debates, discussing use of life skills in a particular situation, using videos and short films, through art, music, and theatre, and decision mapping and problem trees. A combination of these methods can be used depending on available resources, expertise and time. These core life skills are:

- *Self-awareness* This is the ability to identify both our strengths and weaknesses or desires and dislikes. This is required for effective communication and useful interpersonal relationships. This skill is also needed for developing empathy towards others.

**Table 1** Indian Academy of Pediatrics recommendations for vaccination of adolescents

Tetanus toxoid	Booster at 10 and 16 years. It is better to use one dose of Tdap after 10 years and subsequently Td (at 16 years)
Rubella	As part of MMR vaccine or monovalent vaccine, one dose to girls at 12–13 years of age if not given earlier
MMR	One dose at 12–13 years of age if given earlier or two doses at 4–8 weeks interval
Hepatitis B	Three doses (0, 1 and 6 months) if not given earlier
Typhoid	One dose every 3 years (Vi vaccine)
Varicella	One dose up to 12–13 years and two doses (at 4–8 weeks interval) thereafter, if not given earlier
Hepatitis A	Two doses (0 and 6 months), if not given earlier (prior checking anti-HAV IgG may be cost effective)
HPV vaccine	In females up to 15 years 2 doses (0 and 6 months) and >15 years, three doses 0, 1 or 2 (depending on the vaccines) and 6 months

*Abbreviations:* MMR, measles-mumps-rubella; HAV, hepatitis A virus; IgG, immunoglobulin G; HPV, human papillomavirus.

- *Empathy* This is the ability to understand other's real situation or to put ourselves in others' shoes and try to learn the difficulties (or ease) of being in that particular situation. Empathy helps us in understanding people who may be in a very different situation than us or people who are in very different ethnic or cultural diversity. This skill leads us to help people who need help from others like those who have some physical or mental illness or subnormality.
- *Critical thinking* This is objective analysis of situations and information and certainly keeping bias aside. Often writing pros and cons of a situation or likely decision helps in objective analysis. Critical thinking helps us in choosing healthy and useful options and in avoiding harmful situations. It influences our attitude and behavior in dealing with media, peer pressure, and potentially harmful influences.
- *Creative thinking* This skill is related to exploring the alternatives and options available in a particular situation or at a particular point of time. Learning this process helps us in problem solving and decision making. This skill enables us to look beyond our personal experiences, to learn from experiences of others, and to learn responding favorably by adapting our actions. This skill also makes us flexible which is very important as all have to face different circumstances.
- *Problem solving* This is a very important skill and can be learned. One has to use several skills to effectively solve problems. Analysis of various aspects of a problem (or issue) and the available options is the first step in problem solving. Choosing an option based on one's abilities or situation at that point of time is the next step. Implementing the chosen option is the final step in problem solving. Unresolved problems often lead to stress which can in turn have somatic symptoms of anxiety.
- *Decision making* This is a very important skill as it is needed everyday! Adolescents have to make lots of decisions which have lifelong impacts. These decisions may include not choosing friends, opting for particular course or carrier, selecting food items, selecting lifestyle, etc.

Decision-making process includes defining problem(s), identifying consequences of unresolved problem(s), finding solutions and consequences of adopting a solution, choosing a solution and implementing the decision. Writing these steps on a paper helps a lot especially when one is learning the process of decision making. Later this becomes a habit.

- *Interpersonal relationship* We are social beings and interpersonal relationships are integral part of our life. We need to learn to retain useful relationships and to learn ending the relationship amicably if needed. This skill helps us to relate positively with people whom we respect, value and love. These may be our parents, siblings, relatives, teachers and friends. Respecting others as they are and selfless expectations build this skill.

This ability to make and keep friends is a big support for our social and mental well-being. At times, not having good friends or unhappy and failed relationships can prove to be major cause of adolescent anxiety, depression and suicide.

- *Effective communication* Communication is a two-way process and includes the ability to express and also the ability to listen and understand. This skill is expressing oneself verbally and nonverbally directly or indirectly through various means including through social media (Facebook, Twitter, YouTube, etc.) and public media like radio, TV. Mobile phone has become a mode of choice for communication through voice or video calls or short message service or video communications, and group calls. Nevertheless, direct face-to-face communication will never lose its charm and

importance. This skill let us express our opinions, desires, needs and also the fears. This also includes the ability to ask for help, for advice and for providing help in time of need.

- *Coping with emotions* This life skill is the ability to recognize emotions in ourselves as well as in others too. This also includes the ability to be aware that how extreme emotions can influence our attitude and behaviors.

Extreme emotions blunt our skill to appropriate behaviors and decision making. It is advised not to take big decisions [like accepting a job or resigning from it; accepting proposals (or not accepting) for long-term relationships, etc.] when one is under the influence of extreme emotions like happiness or sadness. It is also advised not write letters (or email) during extremes of emotions. Inability to handle appropriately the strong emotions like anger and sorrow can lead to inappropriate or antisocial behavior. This may lead to soar relationships and can also potentially affect mental and physical health.

- *Coping with stress* Stress is integral part of our life. Mild or healthy stress can improve our behavior and timely completion of assignments whereas inappropriate or excessive stress (inadequate handling of mild stress) can be harmful to our health. This skill includes recognizing the source and triggering factors for stress in our life, identifying its effects on our routines in daily life, and finding the ways of controlling the stress and its effects on us. When stress in unremovable then certain modifications in our lifestyle helps. Stress-busting methods include avoidance of factors leading to stress, meditation, yoga, laughter clubs, participating in group activities, physical exercises, etc.

## FAMILY LIFE EDUCATION

Family life education aims to improve quality of life of individuals in family by providing adequate age-appropriate information, imparting values, and providing skills to use the gained knowledge. In the context of adolescents, this term of FLE has a very useful purpose. There are some aspects of adolescent growth and development which need to be communicated correctly to adolescents. Such efforts have drawn criticism from various individuals and organizations mainly because of its nomenclature. Adolescence education has been termed as sex education or sexuality education and this caused problems in various parts of India. So, adolescence education has been termed FLE.

Family life education sessions are organized where a physician well versed with adolescence issues take these interactive sessions with adolescents, parents and teachers. The topics are chosen depending on the needs of adolescents of the area/school. Generally, session begins with growth and development during adolescence. Physiological growth including puberty and development of secondary sexual characteristics are described in simple age-appropriate terms in a scientific manner. The psychosocial issues are taken up in some details as this is the most frequent less understood subject. Personal hygiene issues are embedded in the discussion. Emphasis is given on keeping oneself clean during menstrual periods, hand washing and taking care of own body. Nutritional issues are discussed in detail including nutritional needs, undernutrition and overnutrition.

Depending upon the interest of the audience topics related to substance use, stress, anxiety and depression are taken up. Routine adolescence issues like friendships, relationships, and participation in group activities and sports are also taken up. Issues related to abuse including sexual abuse are very sensitive and should be raised. Adolescents are encouraged to raise voice against abuse and share it with parents, teachers or other significant adults in their life. Life skills are also discussed and attempts are made to

empower the adolescents to use these life skills. Emphasis is given on assertive skills, saying no, and empathy.

Family life education helps adolescents in preparing for responsible adult roles. It helps parents and teachers in understanding adolescent growth and development and behavior in a better way. It also prepares parents and teachers to negotiate better with adolescents on various contentious issues. FLE helps the whole family and improves quality of life of not only of adolescents but also of parents and others in family.

## PREVENTIVE INTERVENTIONS

For healthy adolescent development, we need to understand and apply certain preventive interventions. These are expected to reduce risk factors and to enhance the protective factors and thus make healthy development more probable. Preventive interventions may be universal, selective and indicated. *Universal preventive interventions* are applied to all population irrespective of existing risk, e.g., media interventions for prevention of use of tobacco; encouraging youth to have physically active life; and avoiding driving vehicles after drinking alcoholic beverages, etc. *Selective interventions* target groups with some enhanced risks, e.g., screening for hyperlipidemia in obese adolescents or in adolescents with family history of hyperlipidemia or coronary artery disease or stroke. *Intended interventions* are for those individuals who already have some features of a disorder or disease or problem behavior, e.g., working with adolescents under detention in juvenile care homes to prevent further involvement in antisocial activities.

Several studies have proven the efficacy of policy interventions like providing contraceptives without parental consent, counseling and sexuality education lead to reduction in adolescent pregnancy, and increasing minimum legal age for drinking reduces drinking and traffic accidents. Randomized controlled trials (RCTs) have found interventions like parent training programs, computer based interventions for parents and adolescents, and family therapy through various means including home visits very useful in reducing smoking, drinking alcohol, and less involvement in crimes. Similarly RCTs showing school based life skills training interventions on decision making, goal setting, anger management, communication, stress reduction, drugs misuse and its consequences reduced smoking and use of alcohol and drugs. Including emotional literacy, self-control, social competence, peer relations, and problem solving skills in school curriculum led to better positive development (e.g., psychological competencies and positive self-identity) and lower level of risk behaviors (e.g., substance misuse and delinquency). These interventions promote interpersonal skills, positive peer relationship and skills to face negative peer influences. These programs lead to development of individual skills and competencies.

These programs demonstrated that targeting reduction in risk factors and enhancement of protective factors lead to healthy developments. Some of the health promoting interventions during adolescence are described here.

## Role of Media

Media influences almost all aspects of adolescence including diet and eating disorders, physical activity and overweight/obesity, behaviors like sex, drugs, violence, suicide, school problem and even sleep. History of media use and media influence is very important and it should be elicited in all adolescent clinical encounters. Two questions should always be asked: How much time do you spend daily on all media (newspaper/magazines/novels, TV, mobile phone and computer)? Is there a TV set and a computer (or smart mobile phone) with access to internet in your bed room? Response to these questions will give a very fair idea of media use by adolescent.

Media has become ubiquitous and newer media in form of internet-enabled mobile phones and handheld computers are in common use. The challenge is to promote use of media in education and promotion of health and values and at the same time avoiding the negative influence and misuse of these interactive media.

Media certainly influences adolescent psychosocial development and behaviors including behaviors related to drugs, sex, food habits and physical activity patterns. Conventional and modern media can be judiciously used to promote various aspects of health promotion in adolescents. Some TV serials have been made based on various health education messages. In clinical practice too counseling process becomes more effective when it is supplemented by showing video or interactive computer program. Video-based programs and smartphone-based interactive apps/softwares are available for various health-related uses. One can find such programs which are useful in delivering intended health promoting messages.

The practitioners need to ask about media use and to advise parents about how to control media use (e.g., keeping TV sets in common place and avoiding TV/computer with internet in adolescent's room), how to use media wisely (e.g., watching TV or other media together and discussing about talking points like drug use, sex and physical activity, etc.) and how to implement media education programs. Even briefly discussing media can be very useful.

## ADOLESCENT EDUCATION PROGRAM IN INDIA

This program was developed by several government agencies and National Council of Education Research and Training coordinated the development of this program and its implementation in schools. The AEP considers adolescence as a positive phase of life, full of possibilities and potentials. It also recognizes that adolescents in India are very heterogeneous group with diversity in terms of urban/rural, caste, class, religion, cultural beliefs, etc.

This program aims to empower young people with accurate, age-appropriate and culturally relevant information, promote healthy attitudes and develop skills to enable them to respond to real life situations in positive and responsible ways.

It prescribes to make adolescents understand their growing body and physical and psychosocial needs learn core life skills in a scientific and culture sensitive manner, to understand and negotiate existing and constantly changing life realities. AEP also makes them aware about various issues related to substance abuse and HIV. AEP is implemented in various government run schools mainly the *Kendriya Vidyalayas*. It is prescribed to influence the entire school curriculum and ethos rather than being an isolated and stand-alone component. The AEP should be introduced in a process which is participatory, process oriented, nonjudgmental, nonprescriptive, nonstigmatizing and not fear inducing. It has inbuilt flexibility in contents and process so as to make it sensitive to the needs of adolescents of a particular school and according to local cultural sensitivities. It is strongly oriented towards transformational potential of education based on principles of social justice and equity.

A concept of *Teen Clubs* is also incorporated in AEP. This includes formation of group of adolescents which meet a prefixed frequency and where adolescents can express themselves freely. These clubs are run by adolescents themselves and are supported by school authorities. Certain issues relevant to member adolescents and society are identified and are taken up in the activities of Teen Clubs. This becomes an informal way of giving messages related to good health for avoiding risks like tobacco consumptions, unhealthy relationships, unprotected sex, etc. In new adolescent health program (*Rashtriya Kishor Swasthya Karyakram*), similar activities have been planned where Peer Educators will be identified and Peer Educators Meet will be organized at least once every 2-3 months. Relevant issues will be dealt with in these meetings. This is an extension of the concept of Teen Clubs.

**IN A NUTSHELL**

1. We need to invest in promotion of health of adolescents to achieve India's health goals including country targets for Millennium Development Goals.
2. General health screening should include identification of risk factors and immunization for the adolescents.
3. Adolescence should be viewed in a life span perspective within dynamic sociological, cultural and economic realities.
4. Sectors like education, social justice, youth empowerment, sports and legislation need to join health sector in promoting health of adolescents.
5. Adolescents need to learn and master the following life skills: self-awareness, critical thinking, empathy, coping with stress and emotions, and interpersonal relationship and effective communication.
6. Adolescent Education Program in India aims to empower young people with accurate, age-appropriate and culturally relevant information, promote healthy attitudes and develop skills to enable them to respond to real life situations in positive and responsible ways.

## Chapter 26.2

# Adolescent Counseling

Atul M Kanikar

Counseling psychology is one of the largest subfields in psychology that is centered on offering therapy and aiding clients who suffer from mental illness and psychological distress. Some amount of depression, thought distractions, anxiety, phobias, tendency to experiment and even blues (sadness) are normal for teenager. Intervention is needed only when these troubles augment to an extent of causing emotional disturbance and hindering the mental growth and potential of the individual. The purpose of intervention counseling is prevention, remediation, learning new skills (behavior modification), growth and personality development.

Various thinkers, theories, languages and cultures have given different meanings to the word *counseling*. However, all psychologists agree on the ultimate purpose or aim of counseling, i.e., to help individuals overcome future problems. The Oxford dictionary defines counseling as *the provision of professional assistance and guidance in resolving personal or psychological problems*.

Pérez (1965) gave a popular definition of counseling as an interactive process conjoining the counselee who needs assistance and the counselor who is trained and educated to offer this assistance. This interactive process needs to be initiated, facilitated and maintained by the counselor through feelings of spontaneity, warmth, tolerance, respect and sincerity. Carl Rogers in his book *"Counseling and Psychotherapy"*, has defined counseling as a process consisting of a definitely structured permissive relationship which allows the client to gain an understanding of self to a degree which enables the client to take positive steps in the light of his/her new orientation. Most of the definitions proposed by renowned scholars maintain that counseling is a process which involves bringing about sequential changes over a period of time, leading to a set goal. Over the years, due to exponential growth of various old and new stressors, the scope of counseling has evolved into multiple fields of human life and at all ages (**Fig. 1**).

For the benefit of practitioners, researchers and theoreticians, the Western Interstate Commission for Higher Education (WICHE) led by Parker (1974) has proposed a three dimensional model for the functions or roles of a counselor. This further elaborates and specifies the scope of counseling in the modern world (**Fig. 2**). Laypeople equate counseling to guidance or education or giving advice but the meaning differs in psychology (**Table 1**). Mental health professionals employ various theories of counseling in dealing with their clients with an approach that keeps the *best benefit of client's growth in focus* (eclectic approach). A detailed discussion is beyond the scope of this chapter.

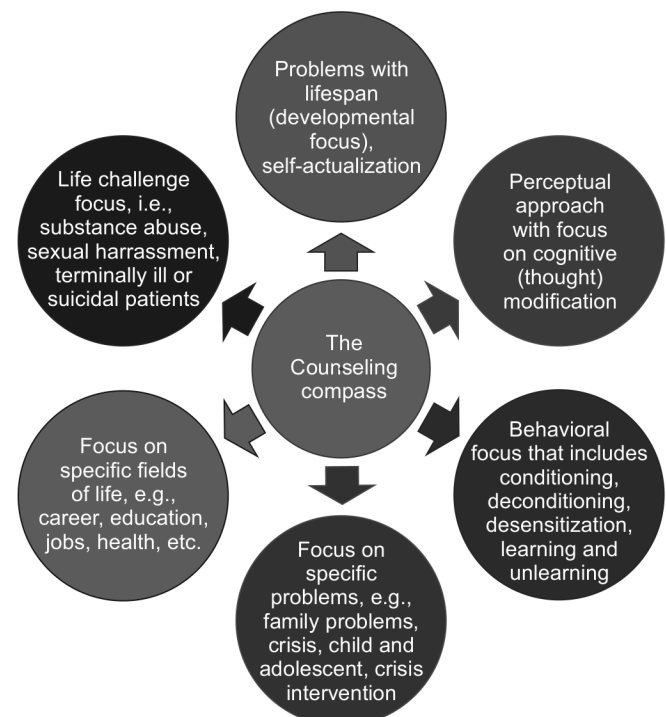

## SPECIAL ISSUES IN COUNSELING ADOLESCENTS

The obvious challenges in counseling adolescents are unwillingness towards therapy, unfriendly attitudes of the therapist, not accepting the problem leading to resistance, tendency to blame the caretakers, social stigma, poor compliance leading to drop outs, peer influence and a feeling of being victimized by parents or teachers. However, many adolescents are quite receptive to the process if the counselor exhibits a skillful and adolescent friendly interview. Further, because adolescence is a stressful period, adolescents need someone who will understand, respect and accept them unconditionally. The counselor must remember that adolescence is a period when basic life philosophies take shape and hence interventions during this period will have a long-term benefit.

## PRINCIPLES OF COUNSELING

Counseling is more of an art than science. Reading about the skills and techniques is easy, understanding them is easier but practicing them consistently is very difficult, if not impossible (**Fig. 3**). The core skills essential for the successful process of counseling are discussed below:

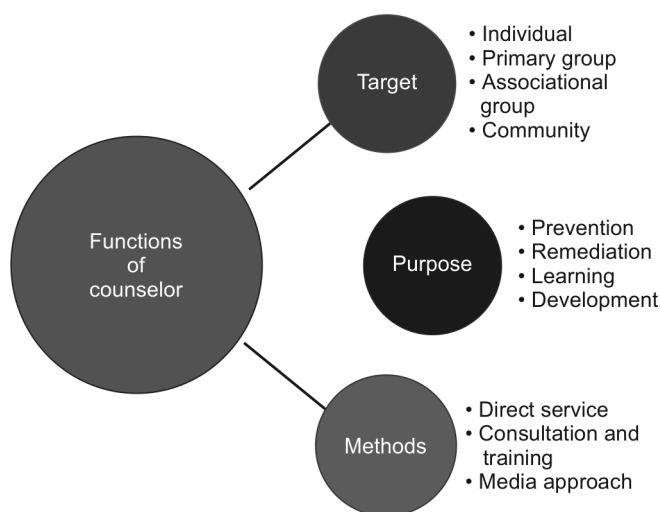

- **Active listening** (see also the subsection on parenting) Most adolescents want and need to be heard and understood, not advised or preached. The counselor must not make interpretations of the client's problems or offer any premature suggestions as to how to deal with or solve the issues presented.
- **Empathy** Empathy is a communicated understanding of the other person's intended emotional message (Martin, 1983). Empathy is also described as putting yourself in the client's shoes without removing your socks and looking at the situation from the client's perspective. Empathy requires listening to and understanding the feelings and perspective of the client and positive regard is an aspect of respect (Carl Rogers). Empathy is not imitation. Dymond (1949) mentions empathy as imaginative transposing of oneself into the thinking, feeling and acting of the client and so structuring the world as the client does.
- **Leading** Also called as *moving the client*. There are several ways to lead the client forward in a session. The counselor needs to be aware of how and in which direction, the discussion is proceeding. Working on the client's issues (and not the counselor's issues) should be prioritized. Responding to the client could be affective (focusing on feelings), cognitive (focusing on thoughts) or behavioral (focusing on the actions and behavior).
- **Self-disclosure** Counselor's self-disclosure is necessary as it relates to the therapeutic process. Too much self-disclosure hinders the counseling process, whereas not enough may inhibit the client from forming a bond with the counselor. For example, at the beginning of adolescent counseling

**Figure 1** The scope of counseling

session, the adolescent should know about the type of cases the counselor handles. This helps to break the ice, relieve the client's nervousness and develop rapport.

- *Using humor* Humor must be used with sensitivity and timing. It should never humiliate or ridicule the client.
- *Immediacy (closeness)* Although counseling can take place anywhere, it is better to have a quiet, comfortable and cozy room without any distractions to ensure effectiveness. All the nonverbal tools of communication (see later) should be employed. Proper distance should be maintained so that both the client and counselor feel safe yet secluded during the process.
- *Transference and countertransference* This is a process wherein the client feels and has perceptions of the therapist that rightly belong to other people in the client's life, either past or present. It is a process somewhat related to *projection*. Understanding transference reactions can help the client gain understanding of important aspects of their emotional life. Countertransference refers to the emotional and perceptual reactions the therapist

**Figure 2** Three dimensional model for counselor's role

**Figure 3** Principles and basic skills of counseling

has towards the client that rightly belong to other significant people in the therapist's life. Sigmund Freud has employed transference and countertransference during psychoanalysis and has mentioned it as an important tool. Transference is the client's projection of past or present feelings, attitudes or desires onto the counselor. It can be direct or indirect and will cause the client to react to the counselor as he/she would in the past or present relationship. Countertransference is the counselor's projected emotional reaction to or behavior towards the client. It can take on many forms, from a desire to please the client, to wanting to develop a social or sexual relationship with the client. When this happens, supervision or counseling for the counselor is necessary.

The counselor should be genuine, interested in helping people, having perceptual sensitivity, normally adjusted in his/her personal life and well trained with good emotional control. A lot of importance is given by Carl Rogers to the term *Acceptance*. He defined acceptance as *a warm regard for the client as a person*

**Table 1** Comparison between guidance, counseling and psychotherapy

	Guidance	Counseling	Psychotherapy
Aim	Making choices/decisions in future for otherwise normal individuals in <i>difficulties</i>	Focus on the present problem in a <i>disturbed</i> individual who is capable of changing into a "fully functioning individual"	Restructuring of personality with focus on the root causes/conflicts originating due to past experiences or mental trauma in mentally <i>disordered</i> individuals
Role of the director/professional	As guide, information provider, supervisor or assistant for short-term only (1–3 sessions)	Purely mental with communicator's and facilitator's role for dealing with the deranged triad of thinking, feeling and behaving. May take 1–15 sessions	Long-term intervention as trained and sometimes dominant authority in exploration and resolution of conflicts or unconscious processes that resulted in severe emotional disturbances in the client/counselee
Problem in the patient/client	Confusion in choices and unclear vocational ideas/concepts	Stress-related situation/crisis which could be due to intra/interpersonal disturbances	Severe mental health disorder (psychosis, severe anxiety, phobias, severe depression, etc.) usually needing pharmacotherapy/electroconvulsive therapy (ECT) in addition
Process	Quantitative analysis, problem-solving techniques and listing of possibilities using information pool	Qualitative as well as quantitative tools and specialty skills which may be cognitive, emotive or behavioral	Mostly qualitative, directive and interpretative due to severity of disorders. Psychoanalysis including dream therapy or cognitive behavior therapy in conjunction with ECT and drugs
Objectives	Educational/vocational/career improvement	Positive self-esteem, capacity building and autonomy for becoming a fully functional and responsible human	Empowerment for adjustment, functionality and improved mental health

of unconditional self-worth and of value under any condition, behavior or feeling. Acceptance implies helping an individual and not controlling him/her.

A counselor must avoid advice giving, lecturing, excessive questioning, storytelling, etc. which may take away the client's interest in the process.

## PROCESS AND STEPS OF COUNSELING (BOX 1)

### BOX 1 The counseling process

- Stage 1: Awareness of need for help
- Stage 2: Development of relationship
- Stage 3: Catharsis and clarification of problems
- Stage 4: Exploration of deeper feelings
- Stage 5: The integration process
- Stage 6: Orientation of time
- Stage 7: Developing awareness or insight
- Stage 8: Termination of contract or referral.

### Stage 1: Awareness of Need for Help

In the Indian context, this is the most crucial step especially in adolescent counseling due to lot of lethargy and wishful ignorance about the extent and severity of mental health problems amongst teenagers and the gatekeepers. Pediatricians, school authorities, media and the administrators have a role to play in creating awareness for the early detection of children and youth with mental health problems.

### Stage 2: Development of Relationship

This is a bridge between personalities of the client and the counselor. The emotionally warm relationship is characterized by mutual trust, liking and respect. The defense may manifest either as the helpless attitude of the client giving all the tasks to the counselor or evoking excessive sympathy and seeking undue attention from the counselor to avoid unpleasant tasks. By exhibiting such defense mechanisms, the adolescent may successfully ward off the counseling relationship especially when brought to counselor's office against will.

### Stage 3: Catharsis and Clarification of Problems

The ventilation of feelings is crucial and the client experiences a sense of relief due to release of tension. This process may further aid in clarification of the problems. However, sometimes the client may have a false sense of resolution of tension, leading to incomplete therapy.

### Stage 4: Exploration of Deeper Feelings

This is a step of *analysis* wherein, the counselor, without remaining satisfied with the superficial view of client's feelings (revealed in stage 3), tries to explore the deeper feelings and conflicting situations which the client was unable to bring to the surface initially.

### Stage 5: The Integration Process

During this stage which evolves smoothly out of stage 4, the client appreciates the feelings and underlying polarities objectively without undue fear, withdrawal or lack of concern. This being a very important step, the counselor has to apply all the necessary skills to help the client to see the feelings from a new perspective. During this process, the counselor can synthesize the needs and potential of the client to direct him/her towards appropriate goals.

### Stage 6: Orientation of Time

Adolescents are usually confused about their time perspective. The counselor helps the adolescent to understand that the present arises logically from the past and has significant influence on the future.

### Stage 7: Developing Awareness or Insight

During this process, the counselor helps the client to gain a new look at self and the world. During psychoanalysis, the counselor aims at providing insight into one's conflicts, repressions and inhibitions and once these are seen from a new perspective by the client, they cease to be painful. Albert Ellis in rational emotive behavior therapy mentions that rational understanding is a prelude for emotional insight.

### Stage 8: Termination of Contract or Referral

The counseling session should start and end on time. It is better to leave 5 minutes for summarizing, assigning homework and setting up next appointment. Termination is the end of the professional relationship with the client when the session goals have been met. A formal termination serves three functions:

1. Counseling is finished and it is time for the client to face his/her life challenges.
2. Changes taken place have generalized into the normal behavior of the client.
3. The client has matured and thinks and acts more effectively and independently.

If the counselor feels that the adolescent has achieved behavioral, cognitive or affective goals; termination is indicated. At times, the clients and counselor may not want the sessions of counseling to end. In many cases, this may be the result of grief or insecurity about losing the relationship. For the client, this is something to process, for the counselor; this is an issue for supervision. For all practical purposes, when pediatricians as counselors suspect a thought disorder, stage 3 substance abuse, severe depression with suicidal ideation, relapse of symptoms with increasing severity or unresponsiveness to their treatment; the adolescent must be referred as early as possible to higher center, clinical psychologist or psychiatrist for further management. In this process, it is the pediatrician's task to convince the parents about the need for referral. The pediatrician can act as a guide and reliable source who can keep the client's follow-ups. In certain instances, adolescents consider the pediatrician as an intermediary to inform their parents about sensitive issues, e.g., pregnancy or love affair and in such circumstances, the pediatrician must ensure the importance of such disclosure to the adolescent in trouble and inform the parents about the situation at hand in the presence of the teenager.

## PARENTING OF ADOLESCENTS

Parenting by definition means an art of bringing up children. It is a bilateral process where both parents and children learn from each other mostly through mistakes. This art is more learnt than inherited. Principal components of parenting are outlined in Table 2.

The factors affecting parenting are educational background of the parents, sociocultural backgrounds, economic well-being, influence of guests/visitors, size and type of the family, mother's profession and her status in the family, methods of family enjoyment and grandparent's role in raising children. Parenting comprises of various tasks, emotions, responsibilities, difficulties and rewards involved in the process of bringing up children (Table 3). It is an ongoing process and will remain so. However, the situation worsens as parent reach middle age when the children enter the stressful period of adolescence and the grandparents face aging disasters. The parents struggling with their careers thus get sandwiched between these two highly sensitive and at times stubborn generations. There is a significant difference in parenting a younger child and an adolescent. Even during adolescence, the early phase, i.e., between 10 years and 14 years, is described as the most difficult to handle by many parents due to unexpected

**Table 2** Principal components of parenting

<i>Important parental task</i>		<i>Methods</i>
1.	Responding to the needs	<ul style="list-style-type: none"> <li>• Caring for children</li> <li>• Spending time and energy for them</li> </ul>
2.	Establishing closeness	<ul style="list-style-type: none"> <li>• Hugging, giving a pat on the back</li> <li>• Holding hands</li> </ul>
3.	Helping to be independent	<ul style="list-style-type: none"> <li>• Giving household responsibilities</li> <li>• Avoiding unnecessary interference</li> <li>• Encouraging them to do tasks independently</li> </ul>
4.	Accepting the individuality	<ul style="list-style-type: none"> <li>• Respecting what a teenager has to say</li> <li>• Considering their point of view especially in family discussions</li> </ul>
5.	Nurturing self-esteem	<ul style="list-style-type: none"> <li>• Avoiding empty praise</li> <li>• Avoiding excessive criticism</li> <li>• Having realistic expectations of what he/she can do</li> </ul>
6.	Accepting our own limitations	<ul style="list-style-type: none"> <li>• Spending quality time together</li> <li>• Having realistic expectations from others</li> <li>• Understanding the ever changing outside world</li> <li>• Knowing our physical and economic constraints</li> </ul>

**Table 3** Parenting responsibilities

1.	Unconditional love	Being on teenager's side, no matter what Separating the teenager from the misdeed Not giving incentives Not bribing them for better results
2.	Keep a close vigil	Monitoring their daily routine Knowing their whereabouts and peer groups Encouraging supervised group activities Interaction with parents of peers Regular visits to the parent-teacher's meetings
3.	Discipline	Maximum use of nonverbal communication Explaining family rules clearly Using time-appropriate rewards Using punishment in proper dose Maintaining consistency and uniformity
4.	Introspection	Parents need to be good role models Accepting teenagers with all their limitations
5.	Crossing the boundaries	Thinking beyond our own family Forming parents' self-help groups Taking professional help if necessary

rebelliousness shown by the teenager. Parental anxiety is also at its peak resulting in strict disciplinary methods, extreme restrictions on the teenager, especially girls, since most parents are not prepared for the changes of menarche that occur usually in early adolescence. A teenager is also very clumsy (due to disproportionate growth) in this period giving rise to many clashes with the family. A teenager is treated simultaneously as a child and an adult, which adds to further confusion. Although technically, parents may not function as ideal counselors, it is the warm, nurturing and safe

home environment which shapes the core personality and yields the desired responsible behavior of an adolescent. If the parents are receptive, exhibit warmth and are good listeners, adolescents in trouble are likely to call them in difficulties. Thus, parents are the first and foremost counselors for children.

## COMMUNICATION SKILLS

Communication by definition is the sharing of feelings, thoughts and information with another person or people through speech, writing, gestures or symbols. Communication has three essential components:

1. Nonverbal
  2. Verbal
  3. Active listening.
- *Nonverbal communication* This major component alone is sufficient many times when dealing with teenagers. Major components are shown in **Table 4**.
  - *Verbal communication* The most traumatizing hurdle of the process of productive communication is improper use of words, initially by parents and then boomeranged by teenagers. However, the task may become easier if parents practice the tips outlined in **Table 5**.
  - *Active listening* Listening includes understanding the feelings and emotions and not merely the spoken words. The four important components of active listening are outlined in **Table 6**. Sometimes crowding of emotions disables the teenager or parents from expressing their feelings. Proper use of pauses and sensible silence helps the communication to become smoother, productive and purposeful. It also gives breathing space for restructuring words, putting thoughts sequentially and understanding exact flow of emotions. Silence can thus be called paradoxically, the most useful tool in interpersonal communication.

**Table 4** Components of nonverbal communication

1.	Eye contact	Ensures confidence, trust and avoids distractions
2.	Facial expressions	Smiling shows that you are interested and even enjoying the process
3.	Position of hands and legs	Open hands and flexed knees reflect openness whereas crossed arms and stretched legs reflect domination
4.	Body movement	Minimum movements avoid distractions
5.	Physical proximity	Holding hands, keeping hand on shoulder, fluffing hair, patting the back, etc. show love, affection and warmth. Touch melts away the fear, uncertainty and chaos in teenagers mind

**Table 5** Tips for good verbal communication

1. Proper use of language	Using the language which if used by the teenager will be tolerated. Parents should be respectful and civil their language
2. Instructions given clearly and assertively	Conveying expectations and values vividly. Making him/her repeat these if necessary without any scope for conflicts due to misunderstandings
3. The KISS principle	"Keep it short and sweet". Avoiding lectures which the teenager learns by heart if repeated often. Short and simple commands are nonirritating and bring out desired effect
4. Use teachable moments	Newspaper articles, advertisements, stories, etc. can be used to initiate discussions. Let the teenager speak out first. Understand what he/she knows, poke his/her eagerness to know further and imbibe values at the end
5. Using "I" statements	"I" statements help the parents convey their feelings and expectations to children. "You statements" sound accusatory and create a resentful feeling. For example, saying, "I am disappointed with the mess in your room and I will be happy to see it clean" is better than saying "you are lazy, careless, lousy, shameless and untidy and you intentionally make me suffer a lot"
6. Open-ended questions for timid teenagers	Questions that begin with how, why, can you describe are likely to get descriptive and elaborate answers, allowing the teenager to open up better. For example, instead of saying "Sex before marriage is bad, isn't it", ask "what do you think about sex before marriage?"
7. Proper use of humor	Not too much but just a dash of humor in a nonhurting way can be very helpful. For example, if the teenager is wearing a short skirt which you do not approve, try saying "Now mosquitoes can really have a great feast"
8. Written notes and chits	Smiling face, dislikes, list of tasks on hand, reminder notes, schedule for the day and sharing feelings and thoughts through letters or chits can help parents and teenagers to effectively and efficiently get their message across

**Table 6** Components of active listening

1. Paying attention	Facing the teenager, minimizing ambient distractions
2. Use of minimal responses	Responses like Ah-ha, Oh, Yes, OK, Right, I understand, Mmm, Hummm enhance continual talk
3. Use of reflection	Helping the teenager to express himself better by paraphrasing what he is saying or trying to say
4. Summarizing	Picking up the key points in the teenager's description of events and emotions and reflecting these back

Because the presenting problem in almost all the child and adolescent clients seen at counseling center is *scholastic*, the adolescent care pediatricians are slowly merging their expertise in the field of educational and career counseling.

## IMPROVING SCHOLASTIC PERFORMANCE

Scholastic achievement is an important developmental task of adolescence. Before one concludes the problem to be purely study related, pediatrician has to rule out certain other possibilities (**Box 2**). Once the cause for scholastic deterioration is sought, the action plan can be formulated with the involvement of parents, teachers and the adolescent client. Patience and consistency must be assured to obtain good results. The key to learning is motivation and it is the counselor's job to work on the adolescent's belief system which acts as a link between thinking and behavior. The task of learning can lead to distress or eustress as illustrated in **Flow chart 1**.

Poor study habits remain the most common cause of scholastic deterioration. The counselor along with a genuinely interested teacher can teach productive study skills to an adolescent. Various tests for assessing intelligence, personality, interests and aptitudes are available and may be employed to gain further knowledge about the etiology and prognosis of scholastic deterioration. Other tests to assess mental health problems like anxiety or depression may also be employed if indicated. Thus, the three areas of intervention can be grouped as given in **Figure 4**.

## Role of Teachers

A teacher counselor is more effective than a teacher and a counselor. A well-trained educational counselor has the following roles to play:

- The counseling role to deal with emotional, educational and vocational planning along with basic life skills education.

He/she is well trained to use various test devices for specific diagnosis of scholastic deterioration.

- The consulting role in collaboration with teachers, parents, educationists, school administrators and pediatricians towards understanding and managing and sometimes referring students. Thus, a well-trained teacher multitasks as an educator, facilitator, consultant and booster for bringing out the best in students.

Different forms of motivation are:

- *Intrinsic motivation* This is motivation from within. For example, I enjoy learning new things; I will be better equipped to obtain a degree.
- *Extrinsic motivation* This is motivation from external forces. For example, my parents will be disappointed if I do not succeed, I will get a pay rise if I finish my degree.
- *Positive motivation* This is nothing but a positive attitude towards the task. For example, I have the ability to get a degree and know that if I do the work, my future income will be much greater when I graduate.
- *Negative motivation* A negative attitude towards the task. For example, My parents will cut off my allowance if I do not study, my friends will think I am stupid if I fail, my family will be disappointed if I drop out.

The most effective forms of motivation are intrinsic and positive. The crowding of emotions, discomfort with self and others, inferiority complexes, etc. all add to the need a counselor in fixing goals. The counselor may categorize goals into the following groups.

**Long-term goals (3–5 years)** Outcomes which an adolescent would like to achieve after completing studies.

**Short-term goals** Outcomes which a student would like to achieve over the next year and up to the completion of the course. These are the stepping stones towards the long-term goals.

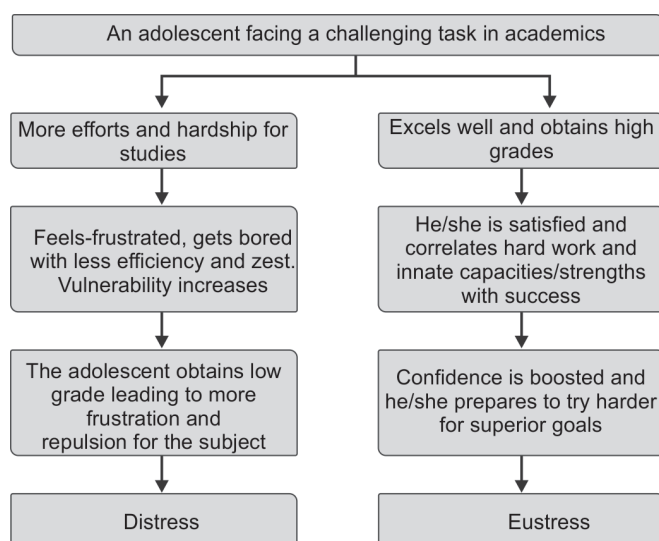

### Why Communication Fails?

- F Fear of the topic (e.g., sexuality or drugs) and being afraid of parental reactions due to authoritarian or very strict parenting style.
- A Assumption about sequence details of discussion due to bilateral prejudices and prototypes.
- I Interruptions. Not allowing the teenager to complete what he/she wants to say. Giving opinions/alternatives without being asked.
- L Labeling the teenager. Calling names and overgeneralization of past mistakes. Not separating the teenager or parents from their misdeeds.
- U Uncertainty about individual abilities to communicate, cooperation from other members and the outcome of dialogue leading to anxiety and chaos.
- R Resentment mainly due to past bitter experiences. Teenagers are touchy about certain issues, e.g., bad company or high-risk behaviors.
- E Ego for both parents and teenager without any empathy. Teenager may feel offended when parents still regard him/her as a child.

### BOX 2 Causes of scholastic deterioration

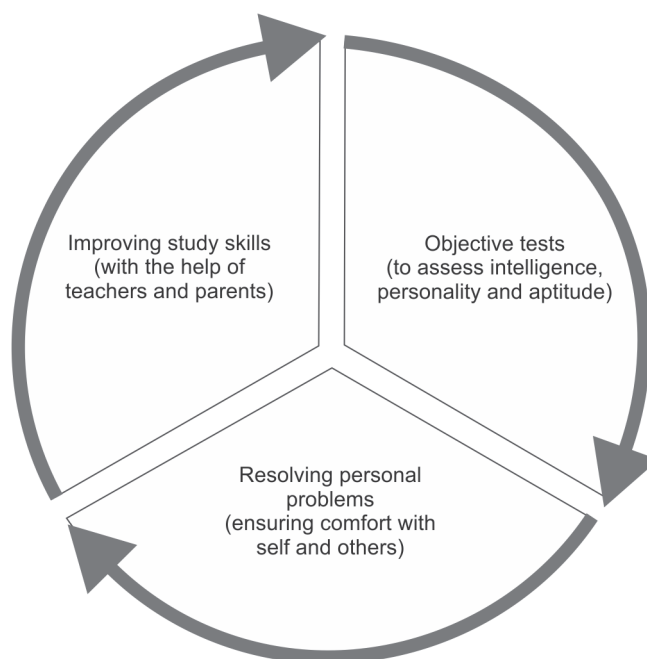

- Physical health-related problems (anemia, refractive error, migraine, infections, delayed puberty, body image concerns, etc.)
- Maladjustment with peers or school teachers (a sense of being victimized, new school)
- Study-related stresses (e.g., poor study skills, learning disabilities and dislike for specific subject, with procrastination tendencies)
- Peer influence (bad company compelling the adolescent to drift away from school work) and desire to identify with peers
- Easily available pocket money which boosts and nurtures various temptations of adolescence
- Broken heart (today's adolescents are maturing early and crushes or intimacies are blooming prematurely)
- Sexual urges and concerns (e.g., masturbation anxiety), drugs and sexual experimentations
- Cyber addictions and excessive, inadvertent and unsupervised use of electronic media including mobile phones
- Poor family communication and other issues at home (abuse, alcoholic parent, financial restraints, terminal illnesses, etc.)
- Depression, anxiety and other mental health disorders.

**Flow chart 1** Consequences of facing an academic challenge

**Mini-goals** Outcomes to achieve by the next day, week or term end. These are stepping stones towards short-term goals. Breaking up larger goals into smaller tasks helps provide a sense of achievement.

BF Skinner has given a very useful therapeutic tool of *homework assignments, practice sessions and shaping techniques*

**Figure 4** Areas of educational counseling

for improving study skills and behavior. AT Beck mentions the role of *solution focused techniques* in scholastic improvement.

The ideas that help sustain motivation are summarized in **Box 3**.

### Preventing Procrastination

The tendency to postpone tasks is almost universal. However, making this a lifestyle can adversely hinder the achievement

### BOX 3 Ideas for motivation

- Affirm and feel that *you can do it!*
- Identify your previous achievements
- Devise a list of all the reasons you originally decided to study. Ensure they are positive and display them in your home and workplace
- Identify your long-term, short-term and mini-goals. Write them down together with your objectives and display these in your home and work place. If you are struggling with motivation, place more emphasis on mini-goals as these tend to be easier to achieve and will help lead to the completion of larger goals
- Construct a realistic study plan and follow it
- Evaluate your time management and decide if you need to develop a more realistic plan to managing your time
- Ensure that your study environment is comfortable and conducive to effective study
- Seek support and encouragement from teachers, family, friends or professionals.

of goals. In reality, thinking about the difficulty in starting or continuing a task is worse than the task itself. Often getting started is the hardest part and so the best way to counter procrastination is to take the first step. Reasons for procrastination are depicted in **Figure 5**.

Fear of failure can be managed by focusing on goal setting and reframing thoughts more positively (I can do it and I should do it). Anxiety about the task can be managed by breaking the task into mini-goals. An adolescent may need assistance to understand the task properly. Time management is crucial for which the tasks will have to be prioritized. Making doable and realistic daily, weekly and semester plans will help. Management of personal issues may need professional intervention and a lot of support from family and peers. Concentration skills can be enhanced by ensuring minimum distractions. The most difficult tasks should be completed when alertness is more. Cooperation from family members and friends is mandatory to minimize distractions and disturbances. Praise for improved efforts boost confidence and self-esteem to make the task achievable and to maintain futuristic thinking.

## CAREER GUIDANCE

In recent times, career guidance has evolved into a specialty and as primary caretakers of adolescents; pediatricians are expected to understand key ideas and referral services for guiding teenagers. Preference for a specific career starts in early adolescence but there is a tendency to shift. By late adolescence, a teenager has a fair idea about his/her career ambitions. The choices are made on subjective factors (values), occupational opportunities, societal acceptability and satisfaction level. Familial and cultural factors also add to these. Vocational development is influenced by physiological, psychological and environmental conditions.

The principal focus of vocational counseling is to plan career options and build motivation to achieve these options by working on specific scholastic tasks and learning new skills. Thus, it is an amalgamation of educational and career counseling. The counselor must have a nonauthoritarian approach and should help the client adopt more positive attitudes and be more realistic in assessing his/her assets and liabilities and gain insight about self. Many teenagers are apprehensive and anxious while making career choices. The counselor should be in a position to provide the latest and complete information about career choices with details of time, money and job opportunities involved. This step is done only after establishing rapport, relieving anxiety, helping him/her gain insights and self-assessment. Vocational guidance gives occupational information while vocational counseling helps the client to self-actualize and be a fully functioning individual in pursuit of his/her occupation. The career counselor has the following functions:

- Assessing the adolescent's abilities, interests, personality features and aptitude
- Facilitating development of specific skills needed for a particular career
- Managing negative emotions like anxiety, helplessness and hopelessness
- Discussing the means to get well adjusted to the new job
- Helping the adolescent in formatting resume and content.

Many times parents and peers govern the type of career that a teenager chooses. Further, in the Indian context, an adolescent girl prefers to give priority to marriage over career. Societal expectations, gender discrimination, poverty, unrealistic expectations of parents and family responsibilities compel many teenagers to choose a career which is easy to obtain and offers substantial financial resource for the family.

**Figure 5** The reasons for procrastination

## PREMARITAL COUNSELING

Family life of a couple many times differs from what it appears to the society. In India, most marriages are arranged and the partners are many times strangers to each other. A period of courtship is not sanctioned by society and the couple interacts with each other freely, few days after the wedlock. The main reason for strained marital relationships is the lack of understanding between partners and little or no empathy. Further, there is no effort to cultivate such empathy by either of the partners. The counselor helps them to gain better understanding of each other as the base for a happy marriage.

Premarital counseling for graduate college students is parallel to family life education in high schools. Today, an individual client is less likely to take help but the counselor can certainly offer group counseling sessions in educational institutions and youth gatherings. Sexual in competency is a very vital area causing conflicts between partners; however in India, nothing can be done in this regard before marriage. An orientation can be given to the couple about family life and various dimensions of human sexuality which are not just aimed at the physical act of sex, but can go up to love, belonging, security, self-esteem and mutual fulfillment. Respect for the opposite gender and willingness to have patience, commitment and active contribution has to be ensured. **Box 4** illustrates the various contributory factors for a happy marriage.

The principal aim of premarital counseling is to avail an opportunity to reevaluate and confirm that a particular partner is the right choice for evolving a stable, reliable and satisfactory married life. The counseling process aims at providing healthy attitudes, delivering scientific information including sexuality education and relieving various anxieties. A battery of laboratory tests recommended before marriage is blood group, enzyme-linked immunosorbent assays (ELISA) for human immunodeficiency virus (HIV), Venereal Disease Research Laboratory (VDRL), hemoglobin electrophoresis, ultrasound of the abdomen and pelvis (in girls). Special tests like metabolic screening and chromosomal studies may be indicated if there is a relevant reason.

### BOX 4 Factors contributing to happiness in marriage

- Freedom with responsibility
- Financial security
- Optimum socialization
- Religious and cultural values
- Interference by relatives
- Occupational choices
- Mutual trust and fulfillment
- Empathy and conflict resolution skills.

**IN A NUTSHELL**

1. Guidance, counseling and psychotherapy are different entities.
2. In spite of rising numbers of mental health problems in India, comprehensive adolescent mental health programs hardly exist and as primary health mentor of adolescents, pediatricians need to take this responsibility.
3. Adolescent counseling encompasses almost all the vital areas including scholastics, life skills, career guidance, premarital issues, mental health disorders, stress management and families. Counseling aims at prevention, remediation, learning and development.
4. Although parents often are not suitable counselors to their adolescents, they should inculcate effective communication skills to enhance adolescent's compliance and growth.
5. Pediatricians must learn the basic skills and steps of counseling with practical and supervised training before taking up the role of counselors.

## Chapter 26.3

# Adolescent Friendly Health Services

Rajesh Mehta, Neena Raina, Patanjali Dev Nayar

Among the people and institutions (government and nongovernment) that have the responsibility of ensuring healthy development of adolescents, health services have a specific role to play. Health-care providers have the direct responsibility of helping adolescents to prevent health problems and provide services, if and when they require, to diagnose and help address their health problems. They must help such adolescents to quickly restore their health by providing appropriate information, advice, counseling and treatment. In addition, health sector must proactively engage with parents, communities, teachers, nutrition programs and social sector for building their capacity to provide accurate and age-appropriate health information and life skills education to, and refer them to health services when needed.

It is a common observation that adolescent girls and boys do not utilize the existing health services even when suffering from one or more health problems or for health concerns. This happens because of several reasons. Many of the adolescents are not even aware of their health problems or that they can seek help from health services. They consider some of the health issues as personal and private (like concerns about penile erection, nocturnal ejaculation or masturbation in case of boys; and vaginal discharge or menstrual problems in case of girls) and do not want their parents to know about. They may be shy and embarrassed that they have such concerns and symptoms related to *private matters*. They are generally hesitant or even scared to contact health-care providers—*Oh, they ask too many questions and do not understand us*. Sometimes the health-care providers are perceived by adolescents to be unkind, judgmental or nonwelcoming. Many adolescents may not know where and how to access the health services; and may not have skills or experience to use health services on their own. They have no financial or social independence to seek health services even when they want to without anyone else coming to know. They do not want to be seen at health facilities from where adults and children also receive services. Sometimes the available services may be too distant.

Knowledge about such barriers for adolescents in utilizing existing health services must be used to design health services that are found welcoming and friendly by adolescent girls and boys.

## ADOLESCENT FRIENDLY ATTRIBUTES OF HEALTH SERVICES

Several attributes of friendly health services have been well identified in global literature. These are described below. Core characteristics are listed in **Box 1**.

### BOX 1 Core characteristics of adolescent friendly health services

- Services are to be readily accessible by adolescents
- Services are to be delivered in an equitable manner to all adolescents, regardless of gender, caste, age and marital status
- Services are to meet expectations and needs of adolescents
- Services are to cover the continuum of prevention and treatment
- Focus on quality of care.

## Provider Attributes

**Staff with appropriate skills** Health-care workers must be trained to acquire skills including clinical competence, interpersonal skills and a positive attitude towards adolescents.

**Privacy and confidentiality** Need for privacy and confidentiality rank very high among the adolescents. Privacy during consultation must be ensured so that no one can see or hear the interaction. Adolescents must feel confident that the health staff (doctor, nurse, counselor or support staff at the clinic) would not reveal their details to their parents or other persons.

**Adequate time for client-provider interaction** Adolescent-provider interactions need more time than adult clients since adolescents need time to open up and to reveal their *personal* concerns. Time is needed to uncover the actual problem, bring myths to the surface, to discuss and dispel them. Therefore, an adequate time should be allotted for each adolescent client.

## Health Facility Attributes

**Separate designated area** Earmarking a designated space for providing services only for adolescents is reassuring for some clients.

**Convenient timings** Adolescents may prefer timings after school hours to utilize health services so that they do not have to miss school or take permission from teachers.

**Safe and convenient location of the clinic** The clinic should be easily accessible and in safe surroundings.

**Privacy during consultation** This ideally requires separate room with doors for consultation and policies that support minimal interruptions and intrusions by other patients or health staff.

**Comfortable surroundings** In general, adolescents prefer a setting that is comfortable, bright, have posters or display material that relates to their taste and interests, and does not present an overly sanitized, hospital like environment.

## Clinic Policies

**Easy registration policies** The clinic registration should be quick and provide option for not having to reveal name or address. The person manning the counter should be friendly and respectful. Need to fill up lengthy forms puts many adolescents off.

**Consultation by drop-in as well as by appointment** Drop-in client's arrangement, which does not need prior appointments help to *seize the opportunity* whenever the adolescent clients show up. However, when requested an early appointment should be made available.

**No or short waiting times** Having to wait for a long time for the doctor dissuades adolescent clients. They have less patience in comparison to adults.

**Free of cost services or affordable fees** Most adolescents are financially dependent on their parents. If they need to pay clinic fees, they would be compelled to reveal the reason to parents for visiting clinic. This is likely to compromise their confidentiality.

**Publicity** The clinic should be widely publicized so that prospective adolescent clients are well informed about the existence of the clinic and services available for them. They must be reassured that they are welcome and will be served respectfully and confidentially.

**Onsite services** The clinic should provide most needed services at the clinic itself as *one-stop shopping* so that most needs are met at one place and they do not need to go from one place to another.

**Necessary referrals available** When essential, the adolescent clients should be referred to expert and clinic that are equally friendly.

Most of the literature on adolescent friendly service emphasizes that changing the attitudes of health-care providers and building their competencies for dealing with adolescent clients should be the first priority. In a large scale, population-based survey among youth in Kenya and Zimbabwe adolescents rated confidentiality, short waiting time, low cost, friendly staff and availability of most services at the same place (minimum need for referral) as most important characteristics for *friendliness*. In Mongolia, the strongest determinant to client satisfaction was reported to be related to acceptability of services; adequate physical environment at the health facility, receiving adequate information about the facility, and if the facility offered privacy.

## BUILDING CAPACITY OF HEALTH-CARE PROVIDERS

It is clear that the knowledge, attitude and skills of a health-care provider are the most critical factor for making adolescent health services friendly. Two main types of skills that are required include the clinical skills and more importantly, interpersonal skills of communication and counseling. The necessary knowledge and skills must be provided to health-care providers during preservice education and training programs (while they are still in medical colleges, nursing and paramedic schools as well as through in-service training while they are already in employment). The World Health Organization (WHO) and other agencies have developed appropriate training materials.

*WHO orientation program (Fig. 1)* is a package that prepares the health-care providers in dealing with adolescent clients differently through interactive participatory training. This builds their knowledge, attitudes and interpersonal communication and

counseling skills to design and provide adolescent friendly health services (AFHS).

*WHO adolescent job aid (Fig. 2)* is an excellent resource to build clinical skills to manage common adolescent conditions as well as reinforce skills in screening adolescents at risk and communicating with parents. It provides algorithms to address most common conditions with adolescent boys and girls present to health services to enable management of such conditions in a standard evidence-based manner. The Part-1 of the Job Aid provides guidelines for the following:

- The special contribution that you could make to health and development of your adolescent patients.
- Establishing rapport with your adolescent patients
- Taking a history of the presenting problem or concern
- Going beyond the presenting problem or concern—HEADSS screening
- Doing a physical examination
- Communicating the classification (possible diagnosis of the condition), explaining its implications, and discussing the management options
- Dealing with laws and policies that affect your work with your adolescent patients.

Part-2 of the Job Aid describes common adolescent health and development issues in algorithms and flow charts, communication tips, information to be given to adolescents and parents, and frequently asked questions. Part-3 of the Job Aid provides guidance on information to be provided to the adolescent and their parents on important topics including: healthy eating, physical activity, sexual activity, emotional well-being, the use of tobacco, alcohol and other substances, unintended injuries, and violence and abuse. Overall,

Figure 1 India adaptation of WHO orientation program

Figure 2 WHO adolescent job aid tool

Adolescent Job Aid is a ready desk reference to enable the trained health-care provider to provide evidence-based management to adolescents for common medical and health conditions.

## NATIONAL HEALTH PROGRAMS IN INDIA FOR ADOLESCENT HEALTH

### National Reproductive and Child Health Program: Adolescent Reproductive and Sexual Health Strategy (2006)

In India, during the National Reproductive and Child Health Program phase 1 (RCH-I), the health-care providers in the public health sector were oriented to the importance and special health needs of adolescents but there were no guidelines on the service provision. Progressing from there, the RCH-II program under the National Rural Health Mission (NRHM) positioned adolescent reproductive and sexual health (ARSH) strategy as one of the key technical strategies besides maternal health, family planning, child health and immunization to meet the overall RCH-II goals of reducing infant mortality rate to 30/1,000 live births by 2012; reducing maternal mortality ratio to 100/100,000 live births by 2012; and reducing total fertility rate to 2.1 by 2012 through: reducing teenage pregnancies, meeting unmet contraceptive needs, reducing number of teenage maternal deaths, reducing incidence of sexually transmitted infections (STIs) and reducing proportion of human immunodeficiency virus (HIV) positive in 10–19 years age group.

The RCH-II ARSH strategy focuses on reorganizing the existing public health system in order to meet the service needs of adolescents. It committed to provide AFHS at the existing health facilities and through outreach activities including preventive, promotive, curative and counseling services. The strategy also emphasizes creation of enabling and adolescent friendly environment in the community for improving accessibility to services and create demand for AFHS. Additional steps are listed below:

- Incorporate adolescent issues in all RCH training programs and all RCH materials developed for behavior change communication
- Identify appropriate indicators related to adolescent health services within the existing health management information system (HMIS) to monitor AFHS
- Intersectoral linkages with National AIDS Control Program and NRHM interventions.

### Implementation of RCH-II ARSH Strategy

All the states in India were supported by the national government to implement the ARSH strategy in selected districts by using the Implementation Guide to implement the seven national standards. Trainings of medical officers were carried out using the national adolescent health training package and rooms identified for running fixed time designated clinics in the health facilities. States used several innovative models like peer-led approaches, community-based and school-based approaches. Thousands of adolescent health clinics were operationalized in existing health facilities with variable utilization of services. Members of professional associations of pediatricians, obstetric-gynecologists and preventive medicine were trained in adolescent health to develop a national pool of trainers for training government and private sector health-care providers. Based on the National Standards for AFHS, the national body of obstetrics-gynecology, the Federation of Obstetric and Gynaecological Societies of India (FOGSI) developed their guidelines for establishing adolescent friendly clinics in the existing practice of their members.

## National Adolescent Health Program under RMNCH+A Strategy (2014)

Based on the experience of implementing RCH-II ARSH strategy in the country and realizing the importance to address the health needs of adolescents beyond sexual and reproductive health the Ministry of Health and Family Welfare has developed a comprehensive adolescent health strategy. The renewed strategy articulates the principles of participation, rights, inclusion, gender equity, and strategic partnerships that would guide its implementation. The vision is stated as: All adolescents in India are able to realize their full potential by making informed and responsible decisions related to their health and well-being.

The strategy identifies seven critical components: (1) coverage, (2) content, (3) communities, (4) clinics (health facilities), (5) counseling, (6) communication and (7) convergence. The interventions and approaches are expected to work towards building protective factors at four major levels: (1) individual, (2) family, (3) school and (4) community. Such protective factors would help adolescents and young people develop *resiliency* to resist negative behaviors and adopt healthy behaviors.

Alongside, the health system would strengthen effective communication in the community, capacity building of service providers and monitoring and evaluation systems. The implementation of such an approach would require a concerted effort by all stakeholder ministries and other institutions including health, education, women and child development, labor, social justice, as well as adolescents, their families and communities.

## MAINTAINING QUALITY OF AFHS

As described above, certain characteristics of health services are critical for attracting the adolescents to seek services and retain them as clients after the first visit. An ongoing monitoring of quality of AFHS would ensure that such adolescent friendly characteristics are actually practiced at the health service delivery points. National standards articulated by Ministry of Health enable assessment of quality of services being delivered from the health facilities. Such standards can be adopted by the private clinic as well. The main purposes of quality improvement process include:

- Measuring the level of performance of health facilities in implementing the AFHS based on the predesigned standards
- Helps identify the gaps and deficiencies of the health-care system and services provided
- Helps identify corrective measures to further improve the quality of AFHS
- Helps strengthen health information system and generating useful information on AFHS.

The World Health Organization has supported assessment of quality of AFHS in India in identified facilities by using a set of assessment tools including observation of health facilities, interview of provider and clients. For example, in Haryana (Fig. 3) and Maharashtra, government health facilities implementing AFHS were found to have higher compliance to the national standards as compared to control health facilities that were not implementing AFHS. Supervisory check lists have also been tried to measure and monitor the quality in an ongoing manner within the system leading to continuous improvement of quality based on the findings of each supervisory visit.

*Disclaimer* The authors are staff members of the World Health Organization. The authors alone are responsible for the views expressed in this Chapter and they do not necessarily represent the decisions, policy or views of the World Health Organization.

**Figure 3** AFHS standards: comparison with control sites in Haryana primary health center  
*Abbreviation:* AFHS, adolescent friendly health services

### IN A NUTSHELL

1. Adolescents are a large proportion of population and are a crucial resource for national development.
2. Contrary to prevalent view that they are healthy, adolescents face specific public health problems that can be prevented and need to be treated urgently.
3. To keep them healthy they need AFHS that they find welcoming and easily accessible.
4. It is important to maintain good quality of the AFHS to sustain utilization by adolescents.
